In this study, BaM films were prepared by the FTS and DCMS systems and they were successively annealed in air to crystallize. It was found that the films prepared by the FTS system are crystallized at lower temperature as compared with the films prepared by the DCMS system. Any preferential crystal orientation was not observed after the annealing

of the films prepared by both systems. The annealed films prepared by the FTS system consist of a single BaM phase, while those prepared by DCMS consist of a BaM and non-magnetic α -Fe₂O₃ phase. Although the reason why the crystallization begins at lower temperature for the films prepared by the FTS system is not clear to date, it suggests that the FTS system has the advantage of practical mass production for the recording medium in comparison to the DCMS system. The magnetic properties for the annealed films are almost isotropic and the values of H_c for the films prepared by the FTS system are from 3 to 5 kOe and higher than those of the films prepared by the DCMS system. Although it is required to control the value of H_c, these values seem to be suitable for ultrahigh density recording media. From the results of XPS measurement it was found that oxidized Fe is reduced to metallic Fe by the high-temperature annealing. This means that partial oxygen gas pressure should be controlled during the annealing process. To clarify the differences in the crystallization process for the films prepared by the FTS and DCMS systems, further experiments should be necessary.

The recording characteristics of Co- γ Fe₂O₃ perpendicular magnetic recording hard disk media were investigated. Sliding contact recording was performed to evaluate the intrinsic high-density recording performance of the media with using a metal-in-gap-type ring head. The half-voltage density D_{50} of 176 kFRPI and low-density reproduced voltage E_p of 143 nV_{p-p}/[turn μ m (m/s)] were obtained for the optimal medium whose Co- γ Fe₂O₃ layer thickness was 0.13 μ m and perpendicular coercivity was 1800 Oe. The pass wear durability test was performed at 2 m/s, or at a disk rotation of 830 rpm. The reproduced voltage did not decrease with time, and scratches and damage were not observed on the tested track even after 18 000 000 passes. The Co- γ Fe₂O₃ medium is one of the candidates for ultrahigh-density recording media because of its specific advantages; superior high density recording performance and hardness tolerable for sliding contact use.

I. INTRODUCTION

After the invention of perpendicular magnetic recording, various types of perpendicular magnetic recording media were proposed.¹⁻⁷ It has been proven experimentally that an extremely high density recording exceeding 500 kFRPI is possible in perpendicular magnetic recording using a Co-Cr perpendicular media.^{8,9} Contact recording is essential to achieve such a high density recording with suppressing spacing loss. There are two ways to achieve contact recording: One is to develop superior overcoat materials, and the other is to develop magnetic thin films for recording layers with sufficient hardness. In the case of Co-Cr medium, an overcoat layer, such as amorphous carbon and SiO_x, is necessary for contact recording because of its insufficient hardness. Oxidized magnetic material is expected to be one of the candidates in the latter approach described above because it is essentially harder than the metallic magnetic materials.

We have already reported that the spinel Co- γ Fe₂O₃ films obtained by annealing the sputtered CoO/Fe₃O₄ multilayers have a large perpendicular magnetic anisotropy, which originates from preferential crystalline orientation of the [100] axis.^{10,11} The perpendicular coercivity of these Co- γ Fe₂O₃ films can be controlled in the wide range from 0.8 to 5.0 kOe. From the viewpoint of magnetic properties, the Co- γ Fe₂O₃ films are applicable to perpendicular magnetic recording media. However, the recording performance for the Co- γ Fe₂O₃ recording media fabricated by this process has never been measured.

In this study, therefore, the feasibility of these films as perpendicular magnetic recording hard disk media in contact recording use was investigated with respect to recording characteristics and pass-wear durability.

II. EXPERIMENT

In the fabrication of Co- γ Fe₂O₃ perpendicular magnetic recording hard disk media, at first, a 0.2 μ m thick NiO layer was deposited on 2.5 in. glass substrate by reactive rf sput-

tering. Successively, CoO/Fe₃O₄ multilayers were deposited on the NiO underlayer at a substrate temperature of 200 °C. Finally, the disks were annealed at the temperatures from 280 to 350 °C to obtain perpendicular anisotropy.¹¹ No overcoat layers were prepared on any of the disks.

The specification of the tested Co- γ Fe₂O₃ hard disks is shown in Table I. In sample series A, the thickness of Co- γ Fe₂O₃ recording layer δ , varies from 0.10 to 0.17 μ m. In series B, perpendicular coercivity H_{c1} , varies from 1472 to 2506 Oe. The metal-in-gap (MIG) ring heads with a gap length of about 0.2 μ m designed for the Hi-band 8 mm VCR were used to measure the recording characteristics. The sliding contact method was introduced to evaluate the intrinsic high-density recording performance of the media.¹²

III. RESULTS AND DISCUSSION

The thickness and perpendicular coercivity dependence of recording characteristics was measured using series A and B samples, respectively, to optimize the media parameters. For all the media, the isolated reproduced pulse shape was di-pulse showing that the perpendicular magnetization mode was realized.

	Sample B6	0.13	2506

FIG. 1. Co- $\gamma\text{Fe}_2\text{O}_3$ layer thickness dependence of half-voltage density (D_{50}) and low density reproduced voltage E_p .

The Co- $\gamma\text{Fe}_2\text{O}_3$ layer thickness dependence of the D_{50} and E_p is shown in Fig. 1. As the Co- $\gamma\text{Fe}_2\text{O}_3$ layer thickness decreases from 0.17 to 0.1 μm , the half-voltage density D_{50} , increases. On the other hand, the peak voltage of the isolated reproduced pulse E_p , decreases with decreasing Co- $\gamma\text{Fe}_2\text{O}_3$ layer thickness. It is necessary to optimize the Co- $\gamma\text{Fe}_2\text{O}_3$ layer thickness according to the density because a tradeoff relation exists between D_{50} and E_p . At densities over 100 kFRPI (kilo flux reversals per inch), the highest reproduced voltage was obtained by using a 0.13 μm thick Co- $\gamma\text{Fe}_2\text{O}_3$ disk.

The perpendicular coercivity dependence of the D_{50} and E_p is shown in Fig. 2. These data were obtained using 0.13 μm thick Co- $\gamma\text{Fe}_2\text{O}_3$ disks. Both for the D_{50} and E_p , the maximum value obtained at the perpendicular coercivity was about 1700 Oe.

Overwrite characteristics were also measured for the 0.13 μm thick Co- $\gamma\text{Fe}_2\text{O}_3$ disks to check the performance for saturation recording. The 36 kFRPI signal was overwritten by a 58 kFRPI signal. Overwrite value, which is defined as the ratio of the 36 kFRPI reproduced signal voltage after and

FIG. 2. Perpendicular coercivity dependence of D_{50} and E_p .

FIG. 3. Overwrite characteristics for 0.13 μm thick Co- $\gamma\text{Fe}_2\text{O}_3$ disks.

before overwrite operation, was plotted against the recording magnetomotive force in Fig. 3. For all the disks with perpendicular coercivity from 1750 to 2338 Oe, the ultimate overwrite value becomes close to -40 dB. This result shows that the recording magnetic field generated by the MIG head is strong enough to perform saturation recording on the 0.13 μm thick disks.

The bit density response curves were shown in Fig. 4. For comparison, the commercialized 2.5-in. longitudinal recording hard disk was also tested. In the longitudinal hard disk, a CoNi recording layer and the 20 nm thick overcoat layer were deposited on a glass substrate. The longitudinal coercivity and the remanent magnetization and thickness product $M_{r\delta}$, of the CoNi layer were 1370 Oe and 2.5×10^{-3} emu/cm², respectively. The D_{50} of 176 kFRPI and E_p of 143 nV_{p-p}/[turn μm (m/s)] were obtained for the Co- $\gamma\text{Fe}_2\text{O}_3$ perpendicular hard disk whose Co- $\gamma\text{Fe}_2\text{O}_3$ thickness was 0.13 μm and perpendicular coercivity was 1800 Oe. These values of D_{50} and E_p were 1.9 and 1.2 times higher than those of the CoNi longitudinal disk.

The pass wear durability test was performed at 2 m/s, or

FIG. 4. Bit density response curves for Co- $\gamma\text{Fe}_2\text{O}_3$ perpendicular magnetic recording disk (\bullet) and CoNi longitudinal magnetic recording disk (\circ).

FIG. 5. Pass wear durability test.

a disk rotation of 830 rpm. The liquid lubricant was applied on the Co- γ Fe $_2$ O $_3$ disk. After the 50.7 kFRPI signal was recorded, reproduction operation was continued with monitoring the reproduced signal voltage. In Fig. 5, the reproduced signal voltage was plotted against the number of disk revolutions. For comparison, a sputtered Co-Cr perpendicular hard disk without an overcoat layer was also tested. The Co-Cr disk was damaged just after the pass wear test started. On the contrary, for the Co- γ Fe $_2$ O $_3$ hard disk, deviation of the reproduced voltage from the initial state was within a few percent, and no scratches or damage were observed even after 18 000 000 passes.

IV. CONCLUSION

A D_{50} of 176 kFRPI and E_p of 143 nV $_{p-p}$ /[turn μ m (m/s)] have been obtained for the Co- γ Fe $_2$ O $_3$ hard disk with optimized thickness and coercivity. It was found that the Co- γ Fe $_2$ O $_3$ disk has pass wear durability over 18 000 000 revolutions in spite of no overcoat.

From these experimental results, it is concluded that the Co- γ Fe $_2$ O $_3$ medium is one of the candidates for ultrahigh-density recording media because of its specific advantages; superior high density recording performance and hardness tolerable for sliding contact use.

Preparation and the magnetic properties of Co- γ -Fe₂O₃ perpendicular magnetic films on NiO underlayer

T. Doi and K. Tamari

R&D Division, Toda Kogyo Corporation, 1-4 Meiji-shinkai, Ohtake, Hiroshima 739-06, Japan

The NiO underlayer, which had $\langle 100 \rangle$ orientation, with NaCl-like structure could be prepared onto the glass substrate by reactive rf sputtering at ambient temperature. The CoO/Fe₃O₄ multilayers were grown epitaxially on the underlayer at 200 °C; the Fe₃O₄ and CoO on the NiO grew along the $\langle 100 \rangle$ axis independent of the bilayer thickness Λ , though those on the glass substrate did not show the $\langle 100 \rangle$ orientation for $\Lambda > 100$ Å. Followed by annealing of the multilayers in air at 280–350 °C, the $\langle 100 \rangle$ -oriented Co- γ -Fe₂O₃ perpendicular magnetic films were obtained. The (400) of the Co- γ -Fe₂O₃ on the (200) of the NiO has tensile stress at the interface because of the smaller (400) spacing than the (200) spacing normal to the film plane. Therefore, the (400) spacing measured parallel to the film plane (2.072 Å) was smaller than that of bulk, 2.086 Å. The magnetic properties of the Co- γ -Fe₂O₃ films on the NiO, Co- γ -Fe₂O₃/NiO, obtained above were evaluated. The squareness compensated by a demagnetization coefficient of Co- γ -Fe₂O₃/NiO were more than 0.94, though those of the Co- γ -Fe₂O₃ on the glass substrate, Co- γ -Fe₂O₃/glass, were about 0.85. The anisotropy energy of Co- γ -Fe₂O₃/NiO was estimated 3.3×10^6 ergs/cm³, which value was larger than that of Co- γ -Fe₂O₃/glass (2.5×10^6 ergs/cm³). Coercivity of the perpendicular hysteresis loop of Co- γ -Fe₂O₃/NiO increased with Co contents and could be controlled in the region of 0.8–5.0 kOe, although H_c of Co- γ -Fe₂O₃/glass were 5.0 kOe constantly. The columnar grains of the Co- γ -Fe₂O₃, whose diameter is 300–500 Å, grew continuously along the columnar grains of NiO.

I. INTRODUCTION

Continuous thin films composed of γ -Fe₂O₃ with a spinel crystal structure have been noted as magnetic recording media because of their high chemical stability, corrosion resistance, large coercivity, and durability due to high hardness. In particular, the perpendicular magnetic films, e.g., the Os doped γ -Fe₂O₃ films obtained by the annealing of the films in an external magnetic field,¹ have been investigated for high-density recording media.

In our previous studies, we have found the preparation method to obtain the Co containing γ -Fe₂O₃, Co- γ -Fe₂O₃, perpendicular magnetic films by control of the crystalline orientation;² For the CoO/Fe₃O₄ multilayers of the bilayer thickness $\Lambda < 80$ Å on the glass substrate, the multilayers indicate $\langle 100 \rangle$ orientation, and $\langle 100 \rangle$ -oriented Co- γ -Fe₂O₃ films can be obtained by annealing of the multilayers in air at 400 °C. The Co- γ -Fe₂O₃ films have a large perpendicular magnetic anisotropy energy, which is induced with the preferential crystalline orientation of $\langle 100 \rangle$ axis.

In the present study, we researched the underlayer that promotes $\langle 100 \rangle$ orientation of the Co- γ -Fe₂O₃. Numerous works show that cubic spinel type crystal can be grown epitaxially on cubic NaCl-like structural materials such as rock salt,^{3,4} single-crystal MgO,^{5,6} CoO on rock salt,⁷ and NiO on single-crystal MgO.⁸ From this point of view, we tried to prepare $\langle 100 \rangle$ -oriented NiO films on the glass substrate, not on the single-crystal substrates, as the underlayer. Furthermore, the magnetic properties of the Co- γ -Fe₂O₃ films prepared onto the NiO underlayer were investigated in comparison with the Co- γ -Fe₂O₃ films on the glass substrate. The microstructures of the Co- γ -Fe₂O₃ films on the NiO were also investigated.

II. EXPERIMENT

NiO films were prepared in Ar+O₂ mixed gas (O₂ pressure, P_{O_2} , was 0.07–0.09 mTorr) onto the glass substrate (HOYA N5) by reactive rf sputtering. The NiO film growth rate was 40 Å/min. CoO/Fe₃O₄ multilayers were prepared onto the NiO film and the glass substrate in Ar+O₂ mixed gas (P_{O_2} was 0.09–0.11 mTorr) at 200 °C by reactive rf sputtering. The multilayers growth rate was 40 Å/min. For the sputtering targets, Ni, Fe, and Co metal disks with 3 in. in diameter were used, respectively. In order to transform the multilayers to Co- γ -Fe₂O₃ films, the heat treatment was carried out in air at 280–350 °C for 1–3 h. The film thicknesses were measured with a surface roughness instrument. The crystal structures and Λ were examined by x-ray diffraction (Fe K α). The magnetic properties were measured with a vibrating sample magnetometer at 20–75 °C. The composition and the depth distribution of composition in the films were analyzed by inductively coupled plasma atomic emission spectroscopy and electron spectroscopy for chemical analysis (ESCA), respectively. Microstructures of the Co- γ -Fe₂O₃ films on the NiO were observed by scanning electron microscope (SEM).

III. RESULTS AND DISCUSSION

NiO films prepared at 25 °C showed $\langle 100 \rangle$ orientation [Fig. 1(a)], though the films at 200 °C had $\langle 111 \rangle$ orientation. It revealed that the $\langle 100 \rangle$ -oriented NiO could be obtained at lower temperature than other NaCl-like structural oxide such as $\langle 100 \rangle$ -oriented MgO which were prepared at 310–750 °C.⁹ Figure 2 shows the relationship between the NiO film thickness, δ_{NiO} , and the intensity ratio, $I_{(200)}/I_{(111)}$, in the x-ray diffraction spectra of NiO. For the

FIG. 1. X-ray diffraction spectra (Fe $K\alpha$) of (100)-oriented NiO film of 1200 Å in thickness prepared onto the glass substrate at 25 °C (a), CoO/Fe₃O₄ multilayer ([CoO(34 Å)/Fe₃O₄(165 Å)]₁₀) prepared onto the (100)-oriented NiO (b) and Co-γ-Fe₂O₃ on the (100)-oriented NiO obtained by annealing the multilayer at 350 °C for 2 h (c).

films of $\delta_{\text{NiO}} \geq 800$ Å, $I_{(111)}$ were the same value, about 10 cps, as shown in Fig. 1(a). It is assumed that there is random oriented initial growth layer of 800 Å in thickness, thus the films of $\delta_{\text{NiO}} \geq 1000$ Å were used as the underlayer in subsequent experiments.

X-ray diffraction spectrum of as-deposited CoO/Fe₃O₄ multilayer prepared for $\Lambda = 199$ Å onto the NiO underlayer is shown in Fig. 1(b). This indicates the multilayers are grown epitaxially on the NiO; The Fe₃O₄ and CoO on the NiO grew along the (100) axis independent of Λ , though those on the glass substrate did not show the (100) orientation for $\Lambda > 100$ Å.² The epitaxial growth of these crystals is attributed to good lattice match. The distances between the oxygen atoms in the fcc lattices of NiO, Fe₃O₄, and CoO along (100) direction were 2.089, 2.099, and 2.130 Å, respectively. These

FIG. 2. Dependence of intensity ratio, $I_{(200)}/I_{(111)}$, in the x-ray diffraction spectra on film thickness, δ_{NiO} , of the NiO prepared at 25 °C.

FIG. 3. Magnetic hysteresis loops of (100)-oriented Co-γ-Fe₂O₃ of 1300 Å in thickness with Co/Fe=0.03 on NiO underlayer.

dimensions represent a lattice mismatch between NiO and Fe₃O₄ of 0.48%, between Fe₃O₄ and CoO of 1.46%, all are within 1.5% of one another.

The Co-γ-Fe₂O₃ films obtained by annealing the multilayers on the NiO had (100) orientation as shown in Fig. 1(c). The (400) spacing of the Co-γ-Fe₂O₃ measured parallel to the film plane, $d_{(400)}$, was 2.072 Å. This value is smaller than that of bulk, 2.086 Å, because the (400) of the Co-γ-Fe₂O₃ on the (200) of the NiO has tensile stress at the interface due to smaller (400) spacing than (200) spacing normal to the film plane. Diffusion of Ni atoms in the NiO layer into the Co-γ-Fe₂O₃ was not observed.

The (100)-oriented Co-γ-Fe₂O₃ films on the NiO, Co-γ-Fe₂O₃/NiO, with the Co-γ-Fe₂O₃ film thicknesses varied from 500 to 2600 Å, were perpendicular magnetic films as shown in Fig. 3. The squareness compensated by a demagnetization coefficient of Co-γ-Fe₂O₃/NiO were more than 0.94, while those of the Co-γ-Fe₂O₃ on the glass substrate, Co-γ-Fe₂O₃/glass, were about 0.85. It is considered that a departure of the magnetic easy axis of Co-γ-Fe₂O₃/NiO from a perpendicular direction is smaller than that of Co-γ-Fe₂O₃/glass, reflecting the importance of

FIG. 4. Coercivity of the perpendicular hysteresis loop, H_c , vs atomic ratio for (100)-oriented Co-γ-Fe₂O₃ on NiO underlayer, (100)-oriented Co-γ-Fe₂O₃ on the glass substrate, and cobalt ferrite films.

FIG. 5. SEM observation of cross section of (100)-oriented Co- γ -Fe₂O₃ film on NiO underlayer obtained by annealing at 300 °C for 2 h.

the (100) orientation. For the films having the coercivity of perpendicular hysteresis loop, H_c , of 5.0 kOe, the anisotropy energy of Co- γ -Fe₂O₃/NiO was estimated 3.3×10^6 ergs/cm³ from the initial in-plane magnetization curve, which was larger than that of Co- γ -Fe₂O₃/glass (2.5×10^6 ergs/cm³), because of the tensile stress described above. H_c of Co- γ -Fe₂O₃/NiO increased with Co contents and could be controlled in the region of 0.8–5.0 kOe, although those of Co- γ -Fe₂O₃/glass were 5.0 kOe constantly (Fig. 4). Additionally, the same H_c could be obtained from Co- γ -Fe₂O₃/NiO films with about one-third the Co content of the cobalt ferrite films prepared onto the glass substrate.¹⁰ It seems that the larger H_c for Co- γ -Fe₂O₃/NiO relative to the cobalt ferrite is caused mainly by a higher extrinsic stress-induced anisotropy due to the larger tensile stress. Temperature dependence of H_c , dH_c^*/dT (here dH_c^* is dH_c divided by H_c measured at room temperature), for

Co- γ -Fe₂O₃/NiO was $-0.266\%/^{\circ}\text{C}$ which was smaller than Co-surface modified γ -Fe₂O₃ powder used for magnetic tapes, $-0.32\%/^{\circ}\text{C}$.¹¹

SEM observation of the cross section of Co- γ -Fe₂O₃/NiO is shown in Fig. 5. The columnar grains of the Co- γ -Fe₂O₃, whose diameter is 300–500 Å, grew continuously along the columnar grains of the NiO.

Co- γ -Fe₂O₃/NiO have the possibilities to be a high-density magnetic recording media, e.g., Co- γ -Fe₂O₃/NiO have a large coercivity, a chemical stability, and high hardness tolerable for sliding contact use with no overcoat, i.e., "0" spacing. Further investigations are now in progress.¹²

Ba-hexaferrite thin films for recording media applications are often fabricated by a two-step process: sputter deposition of an amorphous precursor, followed by annealing to crystallize the $\text{BaFe}_{12}\text{O}_{19}$ phase. The magnetic anisotropy of the crystalline films can be either in-plane or perpendicular, depending on the sputtering process used in the first step. However, conventional structural characterization techniques have not been able to distinguish between different as-sputtered films. Using polarization-dependent extended x-ray absorption fine structure (PD-EXAFS), we have observed anisotropic local structure around both Ba and Fe atoms in the amorphous precursor films. Comparison of the results suggests that the amorphous films consist of networks of Fe atoms surrounded by their O nearest neighbors, with Ba atoms fitting into in-between spaces as network modifiers (there might also be some minor Fe network modifying contribution). The local structural anisotropy of the amorphous films appears to determine the orientation of the fast-growing basal plane directions during annealing, and thus the directions of the c axes and the magnetic anisotropy.

© 1996 American Institute of Physics. [S0021-8979(96)14208-8]

Sputtered barium hexaferrite ($\text{BaFe}_{12}\text{O}_{19}$) thin films show considerable promise for both longitudinal and perpendicular recording media applications. They can be produced with magnetic easy axes distributed randomly in-plane,¹ or aligned perpendicularly,² depending on the sputtering process. The films can either be grown as polycrystalline films by using high substrate temperatures,^{3,4} or deposited as amorphous films, then crystallized by postdeposition annealing.^{1,2} In the two-step process, the crystalline texture and magnetic anisotropy of the crystallized film depend on the sputtering process used to deposit the amorphous precursor. However, x-ray diffraction, electron diffraction, and transmission electron microscopy cannot distinguish between different amorphous films that will crystallize with different magnetic anisotropies.

In a previous paper, we reported the first measurements of local structure and structural anisotropy in amorphous precursor Ba-Fe-O films, using polarization-dependent extended x-ray absorption fine structure (PD-EXAFS).⁵ This technique provides an element-specific probe of local atomic structure, weighted in the direction of the x-ray electric polarization vector. Results show that the as-sputtered films are not completely disordered, but rather have an ordered local structure around the Fe atoms. That structure consists of two main features: a peak corresponding to Fe-O nearest neighbors (comparable in amplitude to that of the crystallized films), and a second peak, corresponding predominantly to Fe-Fe neighbors. In addition, the local structure shows significant anisotropy: the films which will crystallize with perpendicular anisotropy show more crystalline-like order in the in-plane direction than perpendicular, and those which will crystallize with in-plane anisotropy show more order in the out-of-plane direction. These results suggest that the direction of greater order determines the direction in which the

fast-growing basal planes form upon crystallization, thus determining the crystalline texture and magnetic anisotropy which develop.

In the present work, we report new PD-EXAFS results on the local structure around Ba in as-sputtered and crystallized Ba-Fe-O films, compare them with our previously reported results for Fe, and discuss what can be concluded about the structure of sputtered amorphous Ba-Fe-O films.

The films of this study were sputter deposited from sintered oxide targets onto SiO_2/Si substrates at ambient temperature. Films which crystallize with perpendicular anisotropy were deposited by conventional rf magnetron sputtering; in-plane anisotropy films were deposited by reactive rf diode sputtering. Some films were then crystallized by annealing in air at 800 °C for 3 h (see Refs. 1 and 2 for more details).

For each sample, PD-EXAFS data were collected for the Fe K edge and Ba L_{III} edge, using total-electron-yield detection on the X-23B beam line at the National Synchrotron Light Source (NSLS). Spectra were collected using both grazing incidence geometry (which probes structure perpendicular to the film plane) and normal incidence (which probes in-plane structure). For comparison, data were also collected for powder samples of Ba-hexaferrite, Ba-monoferrite (BaFe_2O_4), and BaO (used as empirical standards). The data were analyzed by standard EXAFS analysis procedures,⁶ to obtain Fourier transforms of the EXAFS spectra. In this format, peaks correspond to "shells" of neighbors around the absorbing atoms: the radial coordinate (r) corresponds to distance from the absorbing atom (plus a photoelectron phase shift of 0.3–0.5 Å); the amplitude is related to the number and type of neighbor atoms present at that distance and their atomic disorder.

Fourier-transformed Ba EXAFS spectra for as-sputtered

FIG. 1. Fourier-transformed Ba EXAFS results for as-sputtered $\text{Ba}_{0.03}\text{Fe}_{0.38}\text{O}_{0.59}$ films that will crystallize with (a) perpendicular magnetic anisotropy (PMA*); (b) in-plane magnetic anisotropy (IMA*).

films are shown in Fig. 1. The results show that there is significant local ordered structure around Ba in the amorphous films. In each spectrum, two or three main features can be observed. Comparison with the standard spectra showed them most closely related to features in the $\text{BaFe}_{12}\text{O}_{19}$ standard (and not a good match to the spectra of either BaO or BaFe_2O_4). The first peak in Figs. 1(a) and 1(b) (centered at 2.2–2.5 Å) can be identified from comparison to the $\text{BaFe}_{12}\text{O}_{19}$ standard (Fig. 2), as corresponding to Ba–O nearest neighbors. It is a factor of 2–3 times smaller than it is in the spectra from the crystallized films (Fig. 3), indicating that the relative order around Ba is much less in the amorphous films. The first peak is also shifted to lower r in the amorphous film spectra, indicating that the O nearest neighbors are packed in closer. In the film which will crystallize with perpendicular anisotropy [Fig. 1(a)], it is at 2.4 Å for in-plane structure, and 2.2 Å for out-of-plane structure. In the film which will crystallize with in-plane anisotropy [Fig. 1(b)], it is at 2.4 Å for in-plane structure, and 2.5 Å for out-of-plane structure. In all the crystalline samples (films or powder), it is at 2.5 Å.

The second structural feature in the Ba EXAFS results can be identified as Ba–Fe neighbors. This peak also shows considerably reduced amplitude, and in some cases, large shifts in r . In the as-sputtered film which will crystallize with perpendicular anisotropy [Fig. 1(a)], it is at about 2.9 Å for both in-plane and out-of-plane structure. For the film which

FIG. 2. Fourier-transformed Ba EXAFS results for the $\text{BaFe}_{12}\text{O}_{19}$ powder standard.

will crystallize with in-plane anisotropy [Fig. 1(b)], the out-of-plane structure shows a split peak, with maxima at 3.5 and 3.1 Å. The in-plane structure shows it split even more strongly: one peak is at 3.5 Å; the remainder is seen as a shoulder on the first peak, at about 2.9 Å. In the powder standard, this peak appears at 3.3 Å (Fig. 2); in the crystalline films it is at 3.2 or 3.5 Å (Fig. 3).

The film that will crystallize with perpendicular anisotropy [Fig. 1(a)], shows a third feature (centered at 3.8 Å) in the out-of-plane structure. This would appear to correspond to Ba–2nd Fe neighbors, which in the crystal, are at 4.8 Å (Fig. 2).

Ba and Fe appear to play quite different roles in the structure of the as-sputtered films. In the Fe EXAFS of the amorphous films, the Fe–O peak is comparable in amplitude and at the same r as in crystalline $\text{BaFe}_{12}\text{O}_{19}$.⁵ This indicates that the number and position of O nearest neighbors around Fe atoms is, on average, quite similar to that in the crystal. The structure around Ba, however, shows considerable differences. In the Ba EXAFS of the amorphous films, the Ba–O peak is only 1/2–1/3 as large as the corresponding $\text{BaFe}_{12}\text{O}_{19}$ crystalline peak, and in some of the spectra, it is shifted to lower r . Thus, the Ba atoms in the as-sputtered films do not have as many nearest neighbors as they would have in the $\text{BaFe}_{12}\text{O}_{19}$ crystal (12); nor do those neighbors have the structure (slightly distorted hexagonal close packed) that they would have in the crystal. Similarly, for the second structural feature: In the Fe EXAFS of the amorphous films, the Fe–Fe peak has reduced amplitude and splitting, but is at the same position as that of the crystal.⁵ The Ba EXAFS, on the other hand show either a Ba–Fe peak shifted to much lower r , or two different small Ba–Fe peaks, one shifted and one not. It appears that the structure of the as-sputtered films is made up of networks whose individual units consist of Fe atoms surrounded by their O nearest neighbors. Ba atoms appear to fit into spaces where some of the Fe–O nearest-neighbor units can pack in around them. Thus, it appears that the Fe atoms play the role of network formers, and the Ba atoms the role of network modifiers (although there might

FIG. 3. Fourier-transformed Ba EXAFS results for crystallized $\text{BaFe}_{12}\text{O}_{19}$ films which have (a) perpendicular magnetic anisotropy; (b) in-plane anisotropy.

also be some minor Fe network-modifying contribution). This agrees with what is known about their roles in some glasses,⁷ and in Ba monoferrite.⁸

When Ba has less than the full complement of O nearest neighbors, it appears that the O atoms can pack in closer. This agrees with the observations of the standards. In $\text{BaFe}_{12}\text{O}_{19}$, Ba has 12 O nearest neighbors and the Ba–O peak is at 2.5 Å. In BaFe_2O_4 , Ba has 7 or 11 O nearest neighbors, and the Ba–O peak is at 2.4 Å. In BaO, Ba has 6 O nearest neighbors and the Ba–O peak is at 2.2 Å. Since Ba^{2+} is a little smaller than O^{2-} ,⁹ perhaps the O atoms interfere with each other in the structures with more nearest neighbors. It also appears that when Ba has fewer O nearest neighbors, units of two joined Fe-nearest-neighbor O polyhedra (observed in the Fe EXAFS) can pack in closer. This would appear to explain the big shift of the Ba-2nd Fe neighbor peak in Fig. 1(a).

Local structural anisotropy can also be observed in the Ba EXAFS of the as-sputtered films. In the film which will crystallize with perpendicular anisotropy [Fig. 1(a)], the out-of-plane structure shows a Ba–O nearest-neighbor peak, a Ba–Fe peak, and a Ba-2nd Fe peak all shifted to much lower r than in the crystal. The in-plane structure shows the Ba–O

nearest-neighbor peak at an r value much closer to that of $\text{BaFe}_{12}\text{O}_{19}$, and no low- r Ba-2nd Fe peak. The in-plane structure thus has more crystalline-like order. In the film which will crystallize with in-plane anisotropy [Fig. 1(b)], the in-plane structure shows a Ba–O nearest-neighbor peak shifted to lower r with an amplitude of only about 1/3 that of the crystallized film, and part of the Ba–Fe correlation shifted to much lower r . The out-of-plane structure shows a Ba–O nearest-neighbor peak in the same position as the crystallized film, with a much larger relative amplitude (1/2 that of the crystallized film), and the Ba–Fe correlation has only a small splitting. For this film, the out-of-plane structure appears more crystalline-like. These directions of more crystalline-like order agree with those determined from the Fe-EXAFS.⁵ Apparently during annealing, the fast-growing basal planes form along these pre-existing directions of more crystalline-like order, thus setting up the crystalline texture and resulting magnetic anisotropy.

Local structure has been observed around both Ba and Fe atoms in as-sputtered amorphous Ba–Fe–O films, using PD-EXAFS measurements. Results suggest that the amorphous films consist of networks of Fe atoms surrounded by their O nearest neighbors, with Ba atoms fitting into in-between spaces as network modifiers (there might also be a minor Fe network modifying contribution). The local structure around Ba shows evidence of structural anisotropy, with the indicated directions of more crystalline-like order agreeing with those determined from the Fe-EXAFS. The results suggest that the local structural anisotropy of the amorphous films determines the orientation of the fast-growing basal plane directions during annealing, and thus the directions of the c axes and the magnetic anisotropy.

We would like to thank K. M. Kemner for collecting the Ba EXAFS data for the BaFe_2O_4 powder standard. This research was carried out in part at the National Synchrotron Light Source, which is sponsored by the U.S. Department of Energy. One of the authors (J.E.S.) was supported by the National Research Council Associateship Program. This research was also supported in part by the National Science Foundation under Grant No. ECD-8907068.

Fabrication and magnetic properties of metal/cobalt ferrite composite thin films

J. G. Na

Division of Metals, Korea Institute of Science and Technology, Sungbuk, Seoul 136-791, Korea

To improve the saturation magnetization (M_s) of cobalt ferrite thin films, metal/cobalt ferrite composite thin films were prepared by controlling the sputtering conditions such as oxygen concentration in sputtering gas, substrate temperature, composition of the thin films. With decreasing the oxygen ratio from 50% to 5% in sputtering gas and increasing the substrate temperature from room temperature to 400 °C, the M_s of the thin films was increased and the coercivity (H_c) decreased. The result was attributed to deposition of the metal/cobalt ferrite thin films. With increasing the metal ratio in the thin films, preferred orientation of (111) of cobalt ferrite was worsened in the thin films. The metal deposited in the thin films was identified as cobalt with (002) preferred orientation. In higher cobalt content than the stoichiometric composition of CoFe_2O_4 , the thin films with high M_s and H_c could be deposited in the wide substrate temperature range of 200–400 °C. We can prepare the metal/cobalt ferrite composite thin films with M_s about 580 emu/cm³ and H_c 1700 Oe by controlled the sputtering conditions. The thin films are thought to be applicable to the magnetic recording media with high recording density. © 1996 American Institute of Physics. [S0021-8979(96)07608-5]

I. INTRODUCTION

Cobalt ferrite thin films are very promising materials for magnetic recording media because they exhibit high crystalline anisotropy energy, good chemical stability and mechanical wear.^{1,2} The excellent magnetic properties of the cobalt ferrite are known to be mainly attributed to the Co ions in a spinel lattice.

Cobalt ferrite has an inverse spinel structure, with half of the Fe^{+3} ions on tetrahedral sites (A sites) and the rest, together with Co^{+2} ions, on octahedral sites (B sites) at room temperature. According to the one-ion crystalline-field model, the strong anisotropy of Co^{+2} ion on the B site originates from incompletely quenched angular momentum, which is attributed to the interaction of the electronic structure of Co^{+2} ions with the crystal field.³

Although the cobalt ferrite thin films have the superior properties for the magnetic recording media, there are some weak points to be solved before their application can be realized. The low saturation magnetization (M_s) of the thin films, less than half of the metallic thin films, is one of them.

In this study, the metal/cobalt ferrite composite thin films were prepared to improve M_s by controlling the sputtering conditions such as oxygen concentration in sputtering gas, substrate temperature, composition of the thin films. Also was investigated the relationship between the microstructures and the magnetic properties of the thin films.

II. EXPERIMENTAL PROCEDURE

Cobalt ferrite thin films were prepared by a reactive sputtering method using a facing targets-sputtering unit. The sputtering gas was the mixture of Ar and O_2 and each gas was introduced into the chamber independently. Targets were composed of 6-cm-diam iron disks (99.9 at. % purity) and cobalt chips (99.9 at. % purity). The cobalt content of ferrite thin films was controlled by adjusting the number of cobalt chips attached on the iron disks. Thermally oxidized Si wa-

fers were used as substrates. Prior to deposition, the targets were presputtered at 1 mTorr for 30 min. Typical sputtering conditions are summarized in Table I.

Structure analysis of the films was done by x-ray diffraction (XRD). The composition and the thickness of the thin films were measured by using an electron probe microanalyzer and a surface profiler (Tencor P-1, Tencor Instruments, CA).

Magnetic properties of the thin films were measured by using a vibrating sample magnetometer (VSM-5, Toei Ind. Co., Japan).

III. RESULTS AND DISCUSSION

Figure 1 shows the variation of magnetic properties of the thin films with oxygen concentration in the sputtering atmosphere. Because the V - I characteristics of the sputtering unit and the deposition rate of the thin films were changed with the oxygen ratio in the sputtering atmosphere, we deposited the thin films in the rate of 200 Å/min by controlling the electrical input power. As can be seen in Fig. 1, the thin films can be divided into three regions. The thin films in the region I represent high M_s and low H_c , while those of the region III low M_s and high H_c . The thin films in the region II show regions characteristics intermediate to I and III. Typical hysteresis loops of the thin films deposited in the sputtering atmosphere of (a): (5% O_2 +Ar), (b): (10% O_2 +Ar), and (c): (50% O_2 +Ar) are shown in Fig. 2. The

hysteresis loops of the thin films (a) and (c) represent the loop shapes of conventional metallic and ferrite thin films, respectively. The hysteresis loops of the thin film (b) shows shapes intermediate to those of the thin films (a) and (c).

Figure 3 represents XRD patterns of the thin films shown in Fig. 2. For the thin film (c), only the peaks corresponding to cobalt ferrite were detected and for the thin films (a) and (b), the peaks corresponding to cobalt ferrite and cobalt metal were detected, which indicates that those films are composed of the ferrite and the cobalt. The higher intensity of the Co peaks of the thin film (a) than those of the thin

FIG. 2. The typical hysteresis loops of the thin films deposited in the sputtering atmosphere of (a): (5% O₂+Ar), (b): (10% O₂+Ar), and (c): (50% O₂+Ar).

FIG. 3. XRD patterns of the thin films deposited in the sputtering atmosphere of (a): (5% O₂+Ar), (b): (10% O₂+Ar), and (c): (50% O₂+Ar).

film (b) reveals that the thin film (a) contains more cobalt metal than the thin film (b) and the result leads to the M_s increase of the thin films in the regions I and II shown in Fig. 1. One can see that the preferred orientation of (111) of the cobalt ferrite is worsened with decreasing the oxygen concentration in the sputtering atmosphere.

It is noteworthy from Fig. 3 that the metal deposited in the metal/ferrite composite thin films was identified as cobalt with preferred orientation of (002), which might be attributed to cobalt being more noble than iron in the oxidation-reduction series.⁴ The result, together with worsening the preferred orientation of (111) of cobalt ferrite in the metal/ferrite thin film with decreasing the oxygen concentration in the sputtering atmosphere, might lead to the decrease of coercivity of the thin films shown in Fig. 1 because the direction of easy magnetization of the cobalt metal and cobalt ferrite vary as $\langle 001 \rangle$ and $\langle 110 \rangle$, respectively.⁵

Figure 4 shows the variation of magnetic properties of the thin films with the composition of the thin films and the substrate temperature. Three compositions, 28.5, 33.7, and 37.8 metal at. % Co-Fe of the thin films shown in Fig. 4 were chosen as the hypostoichiometric, stoichiometric, and hyperstoichiometric compositions of cobalt ferrite in the order of listing. As can be seen in Fig. 4, the M_s of the thin films increases with increasing the substrate temperature, while the H_c of the thin films decreases. The result agrees with the result of Fujii *et al.*⁶ They reported that the oxidation degree of iron oxide thin films was dependent on deposition parameters, e.g., substrate temperature and oxygen partial pressure,

FIG. 4. The variation of magnetic properties of the thin films with the composition of the thin films and the substrate temperature.

and more-oxidized phases were deposited at low substrate temperature. They explained that the result may be attributed to the ratio of chemisorbed O_2 molecules and condensed Fe atoms on the surface of growing film. The substrate temperature influenced the chemisorption in such a way that oxygen partial pressure was effectively raised at lower substrate temperature.

In Fig. 4, one can see that the variation of magnetic properties of the thin films is different with the composition of the thin films. For the hyperstoichiometric composition of 38.8 at. % Co-Fe, the metal/ferrite composite thin films with M_s about 580 emu/cm³ and H_c about 1700 Oe, which might be applicable to the magnetic recording media with high recording density, can be prepared in the wide substrate temperature range of 200–400 °C. The M_s value of metal/ferrite thin films is two to three times higher than that of the conventional cobalt ferrite thin films and the H_c value is comparable to the conventional metallic thin films.^{7,8} For the near stoichiometric or hypostoichiometric compositions of 33.7

and 28.5 at. % Co-Fe, however, the metal/ferrite composite thin films with the predominant magnetic properties for the magnetic recording media can be prepared in the narrow substrate temperature range around 300 °C. As can be seen in Fig. 3, the metal/ferrite composite thin films are composed of the cobalt ferrite and the cobalt metal. The deposition of the cobalt metal in the metal/ferrite thin films may be one of the causes of the wide substrate range for the deposition of the thin films of the hyperstoichiometric composition. The result is thought to be important for the reproducibility of the metal/ferrite composite thin films.

IV. CONCLUSIONS

The metal/cobalt ferrite composite thin films with M_s about 580 emu/cm³ and H_c about 1700 Oe can be prepared by controlled the sputtering conditions such as oxygen concentration in sputtering gas, substrate temperature, and composition of the thin films with a deposition rate of 200 Å/min. With decreasing the oxygen ratio from 50% to 5% in sputtering gas and increasing the substrate temperature from room temperature to 400 °C, the M_s of the thin films was increased and the H_c decreased. With increasing the metal ratio in the thin films, preferred orientation of (111) of cobalt ferrite was worsened. The metal deposited in the metal/ferrite composite thin films was identified as cobalt with preferred orientation of (002). In higher cobalt content than the stoichiometric composition of $CoFe_2O_4$, the thin films with high M_s and H_c could be deposited in the wide substrate temperature range of 200–400 °C.

Co–Cr films prepared by sputtering using electron cyclotron resonance microwave plasma

S. Yamamoto, K. Sato, H. Kurisu, and M. Matsuura

Faculty of Engineering, Yamamaguchi University, Tokiwadai, Ube 755, Japan

The sputtering deposition using an electron cyclotron resonance (ECR) microwave plasma was tried to use in the fabrication of the Co–Cr perpendicular magnetic recording media. As the Ar sputtering gas pressure increased from 4×10^{-2} to 8×10^{-2} Pa, the Co(002) x-ray diffraction peak intensity increased and the half-value width of the rocking curve $\Delta\theta_{50}$ decreased. This result implies that Co–Cr films with high perpendicular orientation and good crystallinity are achieved at high Ar gas pressure. The Co–Cr films deposited at a target to substrate distance of 230 mm had a good preferred crystal orientation ($\Delta\theta_{50}$ less than 4°), high perpendicular magnetic anisotropy (H_k higher than 4 kOe), and high perpendicular coercivity over 1400 Oe even though the Co–Cr thickness is as small as about 50 nm, and no underlayers were introduced. Thus, the ECR sputtering has high potential in the deposition of the Co–Cr films for ultrahigh density recording media. © 1996 American Institute of Physics. [S0021-8979(96)14608-3]

I. INTRODUCTION

An extremely high density recording exceeding 500 kFRPI has already been achieved in perpendicular magnetic recording using a Co-Cr perpendicular media.¹⁻³ It has been proven that such a high recording resolution of Co-Cr films is originated from the compositional separation into Co- and Cr-rich regions in the size range of a few nanometers.⁴⁻⁶ In order to improve the recording resolution further, it is necessary to develop the film deposition technology by which the compositional separation is controlled more precisely.

Recently, an electron cyclotron resonance (ECR) microwave plasma has been developed, and used in the thin-film deposition processing. Compared with the conventional diode sputtering, the ECR sputtering features: (1) generation of dense plasma even at Ar gas pressure as low as 10^{-2} Pa, (2) generation of highly ionized plasma, and its controllable irradiation to the substrate.^{7,8}

Up to now, there have been only a few attempts concerning the application of the ECR sputtering to the Co-Cr film deposition.⁹ Hirono and co-workers¹⁰ have succeeded in reducing the grain size of Co-Cr films with a compositionally separated microstructure, while maintaining high grade magnetic properties by using the ECR sputtering method.

In this study, we have tried the deposition of the Co-Cr films for high density perpendicular magnetic recording media by using the ECR sputtering, focusing on the effects of Ar gas pressure, and substrate location on the crystallographic and magnetic properties.

II. EXPERIMENT

The ECR plasma sputtering deposition apparatus used in this experiment is shown in Fig. 1. The discharge chamber was designed as a TE_{113} resonance cavity. The main coils are arranged around the periphery of the discharge chamber. The

magnetic field of 875 G satisfying the ECR condition is generated in this chamber by these coils. The 2.45 GHz microwave was introduced into the chamber perpendicularly to the chamber sidewall through the waveguide. This waveguide/discharge chamber geometry enables the continuous deposition of the conductive films. Under the ECR condition, high density plasma is generated at Ar gas pressure as low as 10^{-2} Pa. In this discharge chamber/substrate configuration shown in this figure, the plasma stream occurs from the discharge chamber toward the substrate along the magnetic lines of force. A cylindrical target to which the negative voltage, V_a , of -100 V was applied, was placed at the end of the discharge chamber. The composition of the target was $\text{Co}_{80}\text{Cr}_{20}$ wt %. The input microwave power was 300 W. The Co–Cr films with a thickness from 0.025 to 0.35 μm were deposited on the 30 μm thick polyimide substrate at the substrate temperature T_{sub} , of 100° in centigrade. The Ar gas pressure was varied in the range from 3×10^{-2} to 9×10^{-2}

FIG. 1. Cross-sectional view of ECR plasma sputtering deposition apparatus.

FIG. 2. Ar gas pressure dependence of perpendicular magnetic anisotropy field H_k , and in-plane squareness $M_{r\parallel}/M_s$.

Pa. The substrate-to-target distance D_{s-t} was varied from 170 to 230 mm. The plasma with the electron temperature from 5 to 12 eV, and the electron density from 0.6×10^9 to $1.6 \times 10^9 \text{ cm}^{-3}$, was achieved in the above described experimental condition. The deposition rate in our experiments varies from 1.5 to 7.2 nm/min according to Ar gas pressure and target to substrate distance.

The crystallographic and magnetic properties were measured using an x-ray diffractometer and a vibrating sample magnetometer, respectively.

III. RESULTS AND DISCUSSION

At first, the Ar sputtering gas pressure dependence of crystallographic and magnetic properties was investigated for a substrate-to-target distance D_{s-t} of 170 mm. As the Ar gas pressure increased from 4×10^{-2} to 8×10^{-2} Pa, the

Co(002) x-ray peak intensity drastically increased, and the half-value width of the rocking curve $\Delta\theta_{50}$, became a half, showing that the crystallinity and perpendicular orientation of Co c axis has been improved. The Ar gas pressure dependence of perpendicular magnetic anisotropy field H_k , and in-plane squareness, $M_{r\parallel}/M_s$, are shown in Fig. 2. The maximum H_k and the minimum $M_{r\parallel}/M_s$ were obtained at an Ar gas pressure of 8×10^{-2} Pa. The maximum of perpendicular coercivity $H_{c\perp}$, and the minimum of in-plane coercivity $H_{c\parallel}$, were also achieved at Ar gas pressure of 8×10^{-2} Pa. These results show that the highly perpendicularly oriented Co-Cr films with high perpendicular orientation and magnetic properties desired for high density perpendicular recording have been prepared at relatively high Ar gas pressure of 8×10^{-2} Pa using ECR sputtering.

To clarify this phenomenon, the probe diagnosis for the ECR plasma was performed. From the V - I characteristics, it was found that both the floating potential of the substrate V_f , and the plasma potential V_s , decrease with increasing Ar gas pressure. Some of the Ar ions in the plasma are accelerated by the voltage difference between V_s and V_f , i.e., $V_s - V_f$, and move along the magnetic lines of force, and finally bombard the substrate. It is surmised that the excessive amount of Ar ion bombardment to the substrate at low Ar gas pressure disturbs the crystal orientation, and consequently, the H_k and $H_{c\perp}$ are low.

In the next step, optimization of the substrate-to-target distance D_{s-t} was performed at an Ar gas pressure of 8×10^{-2} Pa. The D_{s-t} was varied from 170 to 230 mm. The Co-Cr films with half-value width of the rocking curve $\Delta\theta_{50}$, less than 4° were obtained around D_{s-t} of 170 and 230 mm. However, the in-plane M-H hysteresis loops of the films are different in each other as shown in Fig. 3. The in-plane M-H loop for the film deposited at D_{s-t} of 170 mm

FIG. 3. M-H hysteresis loops of Co-Cr films in perpendicular direction (solid line) and in-plane direction (dashed line); (a) is for deposition at substrate-to-target distance D_{s-t} , of 170 mm, and (b) for deposition at D_{s-t} of 230 mm.

FIG. 4. Thickness dependence of $\Delta\theta_{50}$ and H_k of Co-Cr films deposited at optimal condition, i.e., D_{s-t} of 230 mm and Ar gas pressure of 8×10^{-2} Pa.

has jump at low magnetic field as shown by the broken line. This jump is caused by the existence of a low coercivity initial layer in which the Co c axis does not align in perpendicular direction.^{11,12} In the conventional diode sputtering methods, it is difficult to eliminate this nonoriented initial layer unless the underlayer such as Ti and Cr are introduced. On the other hand, for the films deposited by the ECR sputtering at D_{s-t} of 230 mm, no jumps are observed as shown by the solid line because the Ar ion bombardment during deposition is so small that the crystallinity and crystal orientation are not disturbed.

The thickness dependence of the $\Delta\theta_{50}$ and H_k is shown in Fig. 4. These Co-Cr films are deposited at D_{s-t} of 230 mm and at an Ar gas pressure of 8×10^{-2} Pa. As the Co-Cr thickness increases from 27 to 50 nm, the $\Delta\theta_{50}$ drastically decreased and reached a near plateau value of around 3° at a thickness of 90 nm. H_k increased sharply in the thickness range 27 to 50 nm and showed a relatively small increase about 90 nm. Surprisingly, very small $\Delta\theta_{50}$ of 3.1° was obtained at a thickness of 90 nm.

The thickness dependence of the perpendicular coercivity, $H_{c\perp}$, is shown in Fig. 5. The open circles are for the films

FIG. 5. Perpendicular coercivity $H_{c\perp}$, as a function of Co-Cr film thickness. Open circles are for ECR sputtering deposition, and solid circles are for magnetron diode sputtering deposition.

deposited by the ECR sputtering condition tuned at D_{s-t} of 230 mm and at Ar gas pressure of 8×10^{-2} Pa. For comparison, the data for the Co-Cr films prepared by magnetron diode sputtering at the optimal sputtering condition, i.e., Ar gas pressure of 5×10^{-1} Pa, are plotted by solid circles. In both sputtering depositions, the same polyimide substrate was used, and the underlayers which play a role to control the Co crystal orientation were not introduced. Although the films prepared by conventional magnetron sputtering needs at least 100 nm thickness to achieve perpendicular coercivity higher than 1000 Oe, in the ECR sputtering, only 50 nm thickness is enough to realize 1400 Oe coercivity. This is considered by the authors as the specific advantage of the ECR sputtering over the diode sputtering for the Co-Cr films for perpendicular recording.

IV. CONCLUSION

The ECR sputtering deposition technique was used in the fabrication of the Co-Cr perpendicular magnetic recording media. The Co-Cr films with superior crystallinity, perpendicular orientation, and magnetic properties desirable for high density recording were achieved at a high Ar gas pressure of 8×10^{-2} Pa. The Co-Cr films deposited at a target to a substrate distance of 230 mm showed good crystal orientation ($\Delta\theta_{50}$ less than 4°) high perpendicular magnetic anisotropy (H_k higher than 4 kOe), and high perpendicular coercivity over 1400 Oe even when the Co-Cr thickness was as small as about 50 nm. We conclude that the ECR sputtering has high potential in the deposition of the Co-Cr films for ultrahigh density recording media.

Magnetic viscosity and switching volumes of annealed Fe/Pt multilayers

C. P. Luo, Z. S. Shan, and D. J. Sellmyer

Behlen Laboratory of Physics and Center for Materials Research and Analysis, University of Nebraska,
Lincoln, Nebraska 68588-0113

Magnetic viscosity and the phenomenon of the sweep-rate dependence of the coercivity are important for the characterization of magnetic recording media. The activation volume of magnetization reversal or switching volume is directly related to medium noise. The magnetic viscosity behavior of annealed Fe/Pt multilayers was studied and the switching volumes were obtained by both measurements of the sweep-rate dependence of coercivity and time dependence of magnetization. It is found that samples with larger coercivities have smaller switching volumes, and an estimate of the magnetic grain diameter is about 9 nm. The coercivity mechanisms are also discussed. © 1996 American Institute of Physics. [S0021-8979(96)07808-8]

I. INTRODUCTION

Magnetic viscosity parameters are directly associated with the microscopic structure of materials and with the processes responsible for magnetization. The analysis of magnetic viscosity may allow a better understanding of magnetization reversal and coercivity mechanisms. For magnetic recording media, the activation volume of reversal or switching volume is an essential parameter which is related to the media noise. Previously, we have reported that annealed Fe/Pt multilayers with fct structure have large in-plane coercivities and fine grain sizes,¹ which suggests potential applications in future ultrahigh-density magnetic recording. In this work, we studied the magnetic viscosity properties and the switching volumes of the annealed Fe/Pt multilayers.

II. MAGNETIC VISCOSITY

The phenomenon of magnetic viscosity has its origins in thermal agitation of magnetic moment over energy barriers. In many materials it is found experimentally that

$$M(H, t) = M(H, t_0) - S(H) \ln(t), \quad (1)$$

where $S(H)$ is the viscosity coefficient. According to Street and Woolley,²

$$S(H) = \chi_{\text{irr}}(H) H_f(H), \quad (2)$$

where χ_{irr} is the irreversible susceptibility characterizing the barrier hopping and H_f the fluctuation field which is defined by

$$H_f(H) = k_B T / [V^*(H) M_s], \quad (3)$$

where $V^*(H)$ is the activation volume of reversal, $k_B T$ the Boltzmann energy, and M_s the magnetic moment per unit volume.

Another aspect of the time-dependent behavior is the sweep-rate (dH_a/dt) dependence of the coercivity. Higher sweep-rate measurements generally give larger values of H_c than lower sweep-rate measurements. Under certain assumptions, the coercivity varies linearly with respect to $\ln(dH_a/dt)$:³

$$H_c = k_B T / (V^* M_s) [\ln(dH_a/dt) + \text{const}]. \quad (4)$$

The activation volume V^* can be obtained from the slope of the $H_c \sim \ln(dH_a/dt)$ plot.

III. SAMPLES AND MEASUREMENTS

Fe/Pt multilayers were deposited by rf and dc sputtering on cover glasses and annealed at 300 °C for 30 min. The base pressure of the sputtering system was 2×10^{-7} Torr and the Ar pressure was 5 mTorr during deposition. All magnetic measurements were made using a Micromag-2900 alternating gradient force magnetometer. For each measurement of the time dependence of magnetization, the sample was initially saturated with a positive field of 10 kOe, and then a constant negative test field was applied. In order to obtain the $\chi_{\text{irr}}(H)$ curves, the dc demagnetization (DCD) and the isothermal remanence magnetization (IRM) curves were measured.

IV. RESULTS AND DISCUSSIONS

A. Magnetic parameters

The hysteresis loops of the annealed Fe/Pt multilayers with different bilayer thickness (d_b) were measured with applied field in the film plane. All of the measured samples had the same composition and a total thickness of 150 Å. The magnetic parameters such as coercivity (H_c) and squareness (M_r/M_s) are listed in Table I. Rather square hysteresis loops have been obtained for all samples. The table also shows that the coercivities are strongly dependent on d_b , which will be discussed later.

Figure 1 shows the $\chi_{\text{irr}}(H)$ curves of the examined samples, which were obtained by differentiating the DCD and IRM curves, respectively. According to O'Grady⁴ and Donnet *et al.*,⁵ the IRM differential (χ_{irr}^i) measures the distribution of energy barriers to wall motion; while the DCD differential (χ_{irr}^d) measures the energy barrier to domain nucleation in the first instance and then examines the mechanism by which reversal proceeds. Thus, both quantities provide direct information about magnetization reversal, and their relations to coercivity and activation volume will be discussed later.

B. Magnetic viscosity properties

1. Sweep rate dependence of H_c

Measurements of the coercivities as a function of sweep rates were carried out for samples A, B, C, and D with sweep rates varying from 10 to 1000 Oe/s. The results shown in

TABLE I. The magnetic parameters and switching volumes of the annealed Fe/Pt multilayers.

Samples ^a	A	B	C	D	E
d_b (Å)	15	30	37.5	50	75
H_c (Oe) ^b	934	2220	2560	3140	1140
M_r/M_s	0.85	0.89	0.87	0.87	0.85
$V^*(\times 10^{-18} \text{ cm}^3)^c$	6.96	1.42	1.93	1.20	...
$V^*(H_c)(\times 10^{-18} \text{ cm}^3)$	2.03	1.51	1.33	1.25	2.42

^aSamples are: A: (Fe 8.2 Å/Pt 6.8 Å)₁₀; B: (Fe 16.4 Å/Pt 13.6 Å)₅; C: (Fe 20.2 Å/Pt 17.3 Å)₄; D: (Fe 27.4 Å/Pt 22.6 Å)₃, and E: (Fe 40.4 Å/Pt 34.6 Å)₂. All samples are the same total thickness and were annealed at 300 °C for 30 min.

^b H_c was measured at a sweep rate of 250 Oe/s.

^c V^* was determined from the measurement of the sweep-rate dependence of coercivity.

^d $V^*(H_c)$ is the switching volume when the applied field equals to H_c .

Fig. 2 are that H_c linearly depends on $\ln(dH_a/dt)$. So Eq. (4) can be applied to analyze the results and the switching volumes are obtained, as listed in Table I. A small switching volume of $1.2 \times 10^{-18} \text{ cm}^3$ has been measured for sample D which has a coercivity of 3.14 kOe. As the total film thickness h is 150 Å, the magnetic grain size which is defined as $(V^*/h)^{1/2}$ is about 90 Å.

2. Time dependence of magnetization

Logarithmic time decays have been observed for all samples under constant negative applied fields. As an ex-

ample, Fig. 3 shows the magnetization varying linearly with $\ln(t)$ for sample C under different applied fields. From these plots the viscosity coefficients $S(H)$ were obtained, as shown in Fig. 4. The variation of S with H essentially mirrors the behavior of $\chi_{\text{irr}}(H)$ which gives a measure of irreversible processes in the film.

From $S(H)$ and $\chi_{\text{irr}}(H)$, $V^*(H)$ can be obtained, as shown in Fig. 5. Clearly, $V^*(H)$ is not a constant. It depends on the applied fields. This arises from the fact that the applied field may affect both the height and the distribution of energy barriers. In the low-field region, both A and E have much larger V^* than the other samples, while in the high-field region, all samples tend to have the same V^* . At each sample's coercive field, the sample with larger H_c shows smaller $V^*(H_c)$. The values of $V^*(H_c)$ are matched very well with V^* obtained from the sweep-rate dependence measurement of coercivity except for sample A, for which V^* is a little larger than $V^*(H_c)$.

Both H_c and V^* are related to the magnetization reversal mechanisms which depend on the microstructure. Figure 1 reflects how the distribution of energy barriers varies with d_b . In the low-field region, for samples A and E, the nucleation field is greater than the domain-wall-pinning field as can be seen from the $\chi_{\text{irr}}(H)$ curves. Hence, following the

FIG. 1. Differentiated remanence curves for annealed Fe/Pt multilayers.

FIG. 2. The variation of H_c with sweep rate dH_a/dt .

FIG. 3. Time decay of magnetization in the presence of constant magnetic fields in the direction opposite to the initial magnetization for sample C.

analysis of O'Grady,⁴ once the domain is nucleated it expands quickly, causing a sharp increase in switching volumes. And then the decrease of activation volume with applied field may be associated with the pinning of the movement of the nucleated domain walls.

The coercivity is also related to the exchange coupling between grains. Generally the coercivity increases with the reduction of exchange coupling.⁶ For a system without interaction, χ_{irr}^d and χ_{irr}^i should be identical with $\chi_{irr}^d = 2\chi_{irr}^i$. This suggests that the grains are more strongly exchange coupled for samples A and E, for which the χ_{irr}^i curves increase at lower field than the χ_{irr}^d curves.⁷ The exchange coupling ap-

FIG. 4. The variation of viscosity coefficient S with applied field H .

FIG. 5. The variation of activation volumes with applied field.

pears to be reduced for samples B, C, and D as the $\chi_{irr}^i(H)$ and $\chi_{irr}^d(H)$ curves are centered at the same position. High-resolution transmission electron microscopy (TEM) data on these samples show grain sizes of about 15 nm. The large value of H_c in sample D presumably is connected with a smaller exchange coupling, but the correlation of this with details of the nanostructures awaits further TEM studies.

V. SUMMARY

Through the study of magnetic viscosity behavior of the annealed Fe/Pt multilayers, their activation volumes of reversal were obtained. Films with larger coercivities have smaller switching volumes. Given the small estimated value of the magnetic grain size (~ 90 Å) and the large and controllable coercivities, these films may have potential as new ultra-high-density recording media.

Seed layer induced (002) crystallographic texture in NiAl underlayers

Li-Lien Lee, David E. Laughlin, and David N. Lambeth

Data Storage Systems Center, Carnegie Mellon University, Pittsburgh, Pennsylvania 15213

The magnetic properties of Co alloy thin films are strongly dependent on their crystallographic texture and microstructure which in turn can be controlled by the texture of the underlayer. For Co alloy longitudinal recording media with Cr underlayers, it is desirable to have (002) textured Cr underlayers. Since NiAl has the *B2* structure and has a lattice constant similar to that of Cr, NiAl has the potential to be an alternative underlayer to Cr. However, the (002) crystallographic texture of the NiAl films is difficult to obtain. It is found that the (002) texture in NiAl underlayers can be achieved by employing a seed layer of either (002) textured Cr or MgO. Because of the improved texture a significant increase of the in-plane coercivity in CoCrPt/NiAl films was obtained. © 1996 American Institute of Physics. [S0021-8979(96)07908-4]

NiAl is an ordered phase with the *B2* structure. It has a similar crystal structure and lattice constant as that of Cr. It has been shown by the authors that sputter-deposited NiAl films can be used as underlayers for HCP Co alloy longitudinal recording media.^{1,2} Sputter deposited NiAl underlayers tend to induce good in-plane *c*-axis texture in the overlying Co films through the NiAl (112) preferred oriented film planes. An often asked question is: can the crystallographic texture of the NiAl underlayer be altered?

One of the frequently sought after crystallographic textures for Cr underlayers is (002). It has been argued by Zhu³ that the (002) textured Cr underlayers may render a high signal-to-noise ratio in the HCP Co alloy thin film recording media. Since NiAl and Cr are structurally similar, a (002) textured NiAl may impart a similar benefit. We have tried to raise the substrate temperature during the sputtering of NiAl, a practice often used to achieve the (002) texture in Cr. However, this approach fails to produce the (002) texture in the NiAl film. Other means have to be found. A simple solution to this is by making use of a proper seed layer. A seed layer (sometimes called a precoating) is a thin-film layer that is deposited between the substrate and the underlayer. Seed layers are used for (1) the facilitation of infrared heating of glass substrates, (2) the modification of the topography of the disk substrates for tribological purpose, and (3) inducing preferred crystallographic texture to underlayers.

For longitudinal recording media, seed layers such as Al,⁴ Ti,⁵ Ni₃P, TiSi₂, Cr, C,⁶ Ta, W, and Zr⁷ have been used.

Varying degrees of success have been reported, however, the industry is still in the process of searching for a better seed layer. Because of the similarity in crystal structures of NiAl and Cr, employment of a (002) Cr seed layer, which can be achieved by sputter depositing on to a heated substrate, is another approach to inducing the crystallographic texture of NiAl to (002). Another kind of seed layer which may do the same is MgO.

MgO is an ionic crystal with the *B1* (NaCl-type) crystal structure with a lattice constant of 0.421 nm. It has been shown by Nakamura and Futamoto⁸ that a Cr film deposited on a single-crystal (002) MgO tends to have its (002) plane lying parallel to the film plane due to heteroepitaxial growth. It is easy to obtain a sputter-deposited MgO film with a (002) texture because the (002) plane has the lowest surface energy.⁹ Here, the authors have found that, similar to Cr, NiAl deposited on a MgO seed layer can have the (002) texture.

All films were deposited by rf diode sputtering. The deposition conditions were the same as that of the previous papers by the authors.^{1,2} The MgO films were deposited by rf sputtering of a 99.95 at. % pure MgO bulk target and the deposition rate was 4 nm/min. The HCP Co alloy films used in this study were obtained by sputtering from a CoCr target

with bonded Pt chips. Substrates were biased at -100 V with respect to the target during the deposition of CoCrPt films. EDX analysis of the magnetic CoCrPt film determined the composition to be $\text{CoCr}_{10}\text{Pt}_{18}$. Smooth glass substrates were used. Film thicknesses were determined by profilometry. Surface morphology of the films were checked by atomic force microscopy (AFM). Transmission electron microscopy (TEM) was performed on studying the films' plane-view microstructure. In-plane magnetic properties were measured by vibrating sample magnetometry (VSM). Crystallographic textures were studied by x-ray diffractometry with $\text{Cu } K\alpha$ radiation.

FIG. 3. Coercivity values of the 40-nm-thick CoCrPt vs their NiAl underlayer thickness for MgO seed layers of 0, 5, 10, 20 nm thick.

Table I lists the VSM measurements of the 40-nm-thick CoCrPt films on 100 nm NiAl underlayers on MgO seed layers of various thicknesses. The coercivity increases rapidly and then levels off as the MgO seed layer thickens. The maximum coercivity of 3280 Oe occurs at a MgO thickness of 8 nm. The crystallographic texture of these 40 nm CoCrPt/100 nm NiAl films on MgO seed layers revealed by x-ray diffraction spectra are plotted in Fig. 1. The (002) MgO peak continuously becomes stronger as the MgO layer thickens. However, the intensity of the (002) NiAl peak is not proportional to the MgO thickness. The maximum coercivity film in Table I corresponds to the film with the strongest (002) NiAl crystallographic texture.

AFM studies of the films showed little increase in surface roughness as the MgO seed layer is increased from 2 to 10 nm. However, there is a dramatic increase of the surface roughness as the MgO seed layer reaches 20 nm which is believed to be the main cause for the apparent deterioration of the epitaxy between NiAl and MgO. Figure 2 shows the AFM surface topography plots of 100 nm NiAl films on 10 and 20 nm MgO seed layers on glass substrates. A 20 nm MgO seed layer can roughen the film considerably to form

FIG. 4. X-ray diffraction spectra of the CoCrPt(40 nm)/Cr(100 nm) film and CoCrPt(40 nm)/NiAl(100 nm) films with and without a 10 nm Cr seed layer. These films were all deposited with 260 °C substrate preheating.

FIG. 5. Bright-field TEM micrographs of CoCrPt(40 nm)/NiAl(100 nm) films (a) on a 5 nm MgO seed layer and (b) on a 10 nm Cr seed layer.

surface bumps of up to ~ 150 nm in diameter and ~ 25 nm in height. Because a low flying height is necessary for future high-density recording media, this surface roughening may be problematic. On the other hand, to avoid the stiction of the head slider to the smooth disk the surface of the disk substrate is generally roughened by mechanical and/or chemical texturing. For glass disks, a sputtered texture is often used.¹⁰ With the MgO seed layer the roughness can be tailored by controlling the MgO layer thickness or fine tuning the sputtering process.

Figure 3 is a plot of four sets of coercivity data of the 40-nm-thick CoCrPt films versus their NiAl underlayer thicknesses for MgO seed layers of 0, 5, 20, and 50 nm.

Likewise, a 10 nm Cr seed layer when prepared on a 260 °C preheated substrate induces (002) texture in a subsequent NiAl layer. Figure 4 plots the x-ray diffraction spectra of 40 nm CoCrPt/100 nm NiAl films with and without a 10 nm Cr seed layer and a 40 nm CoCrPt/100 nm Cr film. For comparison, these films were all deposited onto 260 °C preheated substrates. The substrate preheating helps to bring out the (002) texture in the NiAl underlayer with a Cr seed layer as well as the standard pure Cr underlayer. However, no (002) peak is observed in the film with only the pure NiAl underlayer. Table II lists the in-plane bulk magnetic properties of the specimens depicted in Fig. 4. It shows the coercivity of the CoCrPt film on the NiAl underlayer is significantly increased due to the incorporation of the Cr seed layer, similar to the MgO seed layer. However, lower coercivity squareness and M_r/t were observed in the film with a Cr seed layer. With a similar (002) texture, the NiAl underlayer appears to induce a higher coercivity in the CoCrPt film than the Cr underlayer.

Figure 5 compares the TEM bright-field micrographs of

40 nm CoCrPt/100 nm NiAl films on 5 nm MgO and 10 nm Cr seed layers. Although these plane-view micrographs show overlapping NiAl and Co grains, it is obvious that the grain size of the film with a Cr seed layer is more than twice the grain size (180 Å) of the film with a MgO seed layer.

In summary, seed layers of Cr and MgO which can induce the (002) crystallographic texture in the NiAl underlayers were shown to be beneficial to the in-plane coercivity of the CoCrPt films. While Cr seed layers require substrate heating, MgO seed layers do not. Therefore, films on a MgO seed layer have finer grains. Surface roughness can also be tailored by using a MgO layer which can provide sputtered texture to smooth substrates to reduce the stiction of the head to the smooth disk.

To achieve higher areal recording density and at the same time very low cost magnetic media, a preembossed disk is proposed in which servo marks, header signals, and ROM data are formed on a plastic substrate by an injection method.^{1,2} Those media give very attractive features to reduce track pitch comparable to optical disks. A very expensive and low throughput servo writer is not necessary by using such preembossed servo marks. To realize the preembossed disk, a magnetic layer should be prepared by low-temperature deposition. In this paper, we studied the sputtering process and suitable magnetic materials such as CoCrPt/Cr film on plastic substrate. Plastic substrate was made by amorphous polyolefin (APO). The under layer (Cr), magnetic layer (CoCrPt), protective layer (C) are formed by magnetron sputtering without substrate heating. Effects of Pt content, thicknesses of magnetic layer, and under layer were investigated. Results showed that coercivity was achieved to 1900 Oe at Pt about 20 at. %, 30-nm-thick magnetic layer and 200-nm-thick under layer. Recording characteristics of the disk were measured by an MR head. The head has a track width of 3.4 μm and a shield distance of 0.35 μm . The results were $D_{50}=100$ kfc, $C/N=47$ dB (at 75kfc), and a resulting density of 0.7 Gb/in². The signal output from the prepit shows 80% maximum value compared with conventional magnetic bits. © 1996 American Institute of Physics. [S0021-8979(96)45608-4]

Nonlinear partial erasure and its correlation with transition noise in longitudinal thin-film media

Jian-Gang Zhu, Terence Lam, Yansheng Luo, and Xiao-Guang Ye

MINT, Department of Electrical Engineering, University of Minnesota, Minneapolis, Minnesota 55455

Nonlinear partial erasure and the supralinear noise enhancement at high recording densities are the two critical factors limiting linear recording density in longitudinal thin-film disk media. In this paper, via spin stand measurements, nonlinear partial erasure was studied in terms of medium magnetic parameters, such as $M_r T$, H_c and orientation ratio, and recording conditions, such as fly height and write current optimization. It is found that the nonlinear partial erasure and the supralinear noise increase always occur at the same recording density, independent of media magnetic properties and recording condition. © 1996 American Institute of Physics. [S0021-8979(96)14308-4]

I. INTRODUCTION

At high recording densities, longitudinal thin-film media exhibit nonlinear amplitude reduction, referred to as nonlinear partial erasure, in addition to nonlinear bit shift.¹ Since all of the advanced data recovery channels, such as PRML, are based on linear superposition, severe partial erasure can present a significant limitation on the linear recording density. Another recording density limiting factor is the transition noise at high recording densities where the noise rises faster than the initial linear increase.^{2,3} With the introduction of magnetoresistive heads, the recording channel can become medium noise dominated. In this paper, we report a systematic experimental study on the correlation between nonlinear partial erasure and medium noise.

II. EXPERIMENTAL AND ANALYTICAL METHOD

The measurements of nonlinear partial erasure were performed on a high precision air-bearing spin stand tester. In order to avoid head nonlinearity, inductive thin-film heads instead of MR heads were used for all the measurements, even for disks with low $M_r T$ values used in MR applications. To distinguish the nonlinear partial erasure from nonlinear transition shift, all "1"s patterns were recorded on thin-film disks so that the deterministic relative position shift in between adjacent transitions is absent. The nonlinear transition shift becomes a block shift and the intertransition interval is exactly the same as the data pattern of the write current. The nonlinear amplitude reduction is usually referred to as the ratio between the amplitude of an actually recorded all "1"s patterns and the amplitude of all "1"s patterns formed by superimposing isolated voltage pulses at the same intertransition interval. Here, in order to eliminate the impact of electronic noise, this ratio was actually measured in frequency domain using a spectrum analyzer with the method briefly described as the follows.

Assuming the linear superposition holds, the signal spectrum of a recorded all "1"s pattern can be written as

$$V(k) = 2k_0 V(k) \sum_{n=\text{odd}} \delta(k - nk_0),$$

where $k = 2\pi/\lambda$ is the wave number, $k_0 = 2\pi/\lambda_0 = \pi/B_0$ is the fundamental wave number while B_0 is the recording bit

length, and $V(k)$ is the Fourier transform of the isolated voltage pulse. The third harmonic for a recording density at $D_1 = 1/B_1$ is

$$V_{D_1}(k = 3k_1) = 2k_1 V(3k_1).$$

The first harmonic for a recording density three times higher $D_3 = 3D_1$ is

$$V_{D_3}(k = k_3) = 2k_3 V(k_3) = 2 \times 3k_1 V(3k_1).$$

Thus, if the linear superposition holds, we have

$$V_{D_3}(\text{first harmonic}) = 3V_{D_1}(\text{third harmonic}).$$

We define the ratio

$$P = \frac{V_{D_3}(\text{first harmonic})}{3V_{D_1}(\text{third harmonic})}.$$

If the density $D_1 = D_3/3$ is low enough where superposition still holds, P becomes a measure of the nonlinear partial erasure at density D_3 and is closely equal to the nonlinear amplitude reduction of the voltage wave form. A more detailed description of the method can be found in Ref. 4. In this paper, P is referred to as the nonlinear partial erasure and is always plotted as a function of recording density D_3 .

A magnetic force microscope, made by Digital Instruments, was used to image the recorded transition patterns. MFM tips were coated with CoCrTa film for imaging. The resonant frequency of the tips is in the range of 30–70 kHz. The magnetic images were obtained using the frequency detection mode.

A set of selected disks with a range of coercivity and area magnetic moment density were used in the measurement. The magnetic hysteresis parameters are listed in Table I. Thin-film heads with gap length $g = 0.21 \mu\text{m}$, fly height

$d_f = 2.5 \mu\text{m}$, and a track width of $4.5 \mu\text{m}$ were used for all the recording measurements except cases mentioned otherwise. The write current was optimized for voltage amplitude at high linear densities. The medium noise is normalized by the peak amplitude of the isolated voltage pulse.

III. RESULTS AND DISCUSSIONS

A. Partial erasure, transition noise, and percolation

Figure 1 shows the measured medium noise power and measured partial erasure as functions of recording density for disk A. Both the supralinear noise increase and nonlinear partial erasure are well pronounced. The onset of the supralinear noise increase and the onset of the nonlinear partial erasure occur at the exact same recording density. Beyond this density, the partial erasure ratio decreases almost linearly with increasing recording density.

The coincident of the onset density for the two measurement quantities is not accidental. Repeated measurements of over 20 different disks using various thin-film heads at various recording conditions show that the two onsets always occur at the same recording density. A magnetic force microscopy image, shown in Fig. 2, taken at densities in the supralinear noise increase region, clearly shows the onset of the percolation between adjacent transitions that also coincide with the onsets of partial erasure and the supralinear

Magnetic Force Microscopy Image of Recorded Transitions

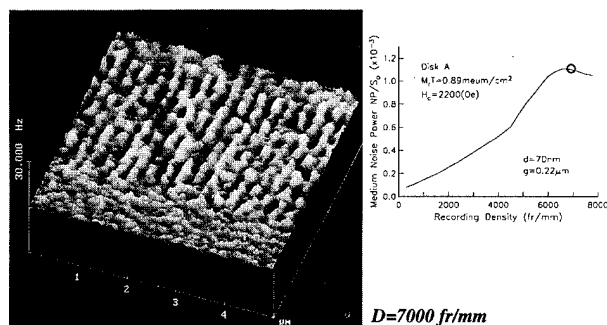

FIG. 2. MFM images of recorded transitions at recording density $D = 7000$ fr/mm for disk A.

FIG. 3. Measured partial erasure P and integrated noise power as functions of recording densities for a highly oriented disk (disk B), and an isotropic disk (disk C).

noise increase. Figure 2 shows the transition image at relatively high density and the intertransition percolation apparently has become well pronounced. From these experimental results, it is concluded that the intertransition percolation is the cause for both the nonlinear partial erasure and the supralinear transition noise increase.

B. Effect of medium orientation ratio

Disks B and C have similar magnetic area moment density and similar coercivity, but with a quite different orientation ratio. Disk B is highly oriented with an orientation ratio of 2.8 while disk C is essentially isotropic. Figure 3 shows the measured partial erasure and medium noise power for both disks B and C. At low densities, the oriented disk exhibits lower medium noise than that of the isotropic disk. At high recording densities, however, the supralinear noise increase for the oriented disk becomes much more pronounced than that for the isotropic disk. The partial erasure of the oriented disk exhibits a significantly steeper slope than that of the isotropic disk.

C. Effect of medium MrT

Disks D and E have similar coercivity, but very different magnetic area moment values: $MrT = 2.5 \text{ memu/cm}^3$ for disk D and 1.3 for disk E. Figure 4 shows the measured partial erasure and medium noise power for disks D and E as functions of recording density. The onset of the partial erasure and supralinear noise increase for the higher moment disk occurs at significantly lower density than that of the lower moment disk. The slopes of the noise increase at low and high recording densities are significantly greater for the higher moment disk than that for the lower moment disk. Such behavior has been observed experimentally³ and also predicted by micromagnetic simulations.⁴ Reducing medium MrT brings the advantage of narrower transition lengths which result in shifting the onset of the partial erasure and supralinear noise increase toward higher recording densities.

FIG. 4. Measured partial erasure P and integrated noise power as functions of recording densities for two disks with different moment densities: disk D ($M, T = 2.5$ memu/cm³) and disk E ($M, T = 1.3$ memu/cm³).

D. Effect of recording fly height

Recording fly height can also significantly affect the partial erasure and the medium noise. In order to study the effect of fly height, two thin-film heads were used, one with a conventional slider and the other with a tripod slider. The recording measurements were performed on disk A. The head-medium magnetic separation is approximately $d = 75$ nm for the head on the conventional slider and $d = 25$ nm for the tripod slider. The two thin-film heads have similar gap length, $g \approx 0.21$ μm and same track width $W = 4.5$ μm . Figure 5 shows the measurements for the two fly heights. The partial erasure starts at a density, $D = 4400$ fr/mm, for the higher flying height case and at $D = 6000$ fr/mm for the lower flying case. The slopes of the medium noise increase at both linear and supralinear regimes are significantly higher for the higher flying case than those for the lower flying one.

E. Effect of write current

Apart from the fly height, write current is another factor which can affect the behavior of both partial erasure and transition noise. Figure 6 shows the measurements for disk F which has relatively low coercivity. At a write current of 6

FIG. 5. Measured partial erasure P and integrated medium noise power vs recording densities for recording at two different fly heights.

FIG. 6. Measured partial erasure P and integrated medium noise power vs recording densities for recording at two different write current amplitudes.

mA at which the high frequency output was optimized, the onset of the partial erasure occurs at $D = 2400$ fr/mm while at a write current of 30 mA, the partial erasure occurs at a much lower density: $D = 1500$ fr/mm. The shift of the onset density of the partial erasure is likely due to broader transitions created by the poor head field gradient.

IV. REMARKS

It is concluded that the onset of the partial erasure is essentially determined by the transition length parameter which is a function of medium magnetic parameters, such as area moment density M, T , and coercivity H_c , and the recording conditions, such as fly height and recording current. Reducing either the medium M, T or the recording fly height reduces the transition length parameter, thereby shifting the onset of the partial erasure towards higher densities.

At high recording densities, nonlinear partial erasure can dominate the medium nonlinearity. Conventional measurement technique of nonlinear transition shift, such as the fifth harmonic elimination method, cannot distinguish the nonlinear partial erasure from the nonlinear transition position shift. At high densities, write precompensation not only compensates for the nonlinear transition position shift, in fact also compensates the nonlinear partial erasure by moving the adjacent transitions further apart.

The magnetic force microscopy (MFM) technique is used to investigate the writing properties of a set of thin-film heads with track widths ranging from 2 to 0.5 μm . MFM images show that track edge percolation occurs at lower densities than on-track intertransition percolation. Track edge percolation results in track edge fluctuations and effective track width reduction. As the head track width is reduced to the near-micron or submicron ranges, the track edges become dominant portions of the track and consequently cause severe degradation of the recording tracks. Track edge percolation is caused by a poor edge field gradient and is possibly enhanced by pole tip corner saturation. In order to achieve high-density narrow track recording, high moment writing heads become necessary. © 1996 American Institute of Physics. [S0021-8979(96)08008-9]

I. INTRODUCTION

Rapid increase of track density requires a much improved understanding of the recording properties for narrow track recording heads. As the track width narrows down to the near-micron or submicron range, not only the properties of the erased band become significant, but also the on-track recording characteristics near the track edges become more and more important.¹⁻³ For conventional thin-film heads, head saturation at the corners of the pole tips does not present a serious problem and has always been neglected since the track width is sufficiently wide. At near-micron or submicron track widths, the head corner saturation phenomenon will be severe and will affect the recording properties more significantly.

To address the above issues, we present a magnetic force microscopy (MFM) study of the recording properties of narrow track thin-film heads. The heads have track widths ranging from 2 to 0.5 μm . The emphasis is to investigate the impact of head width reduction on the writing characteristics, both on-track and at track edges.

II. EXPERIMENT

The recording heads used in this study were fabricated from a set of identical thin-film heads with advanced air bearing (tripad) designs for achieving low flying heights. Using a high precision focused ion beam (FIB) etching technique, the pole tips of these heads were trimmed from the air bearing surface to obtain very narrow track widths. The track widths obtained are 2, 1, 0.75, and 0.5 μm . Figure 1(a) shows the picture of a head before FIB trimming and Fig. 1(b) shows the picture of a trimmed head with 1 μm track width. The trimming depth is 1 μm , approximately the same as the head throat height. The heads all have a gap length $g=0.22 \mu\text{m}$ and a flying height less than 1 μm .

Recording experiments were performed on a precision air-bearing spin stand. The magnetic disk used in this study was a planar isotropic thin-film disk with $Mrt=0.79 \text{ memu/cm}^2$ and $H_c=2200 \text{ Oe}$. The disk was in a dc erased

state prior to recording. The heads all have 42 turns and the recording current used is 10 mA zero to peak at which the overwrite performance was optimized.

A Digital Instruments Nanoscope III TAFM was used to obtain high-resolution images of the recording tracks. MFM tips were coated with CoCrTa alloy for magnetic imaging. The resonant frequency of the tip is in the range of 30–70 kHz. The magnetic images were obtained in the frequency detection mode.

III. RESULTS AND DISCUSSION

A. Properties at low recording densities

Figure 2 shows an MFM image of a track recorded with the 1- μm -wide recording head. The linear density is 2000 fr/mm. As shown in this image, the transitions are well defined both in the on-track region and in the track edge region. The track width is about 0.62 μm measured from the image. In the side regions of the track, the medium remains in the dc erased state. Since these heads are trimmed from the air bearing surface, two shoulders are created on both sides [see Fig. 1(b)]. However, the MFM image in Fig. 2 shows, for the heads we used, 1 μm trimming depth is sufficient to suppress

FIG. 1. Optical microscope images from the ABS for the (a) untrimmed TF head, and (b) trimmed 1- μm -wide TF head.

FIG. 2. MFM images of an isolated track recorded with the 1- μm -wide head at linear density of 2000 fr/mm.

the influence of the fringing fields from the shoulders. The well-recorded transitions and clear track edges indicate the success of the trimming process.

B. Properties at high recording densities

Figure 3(a)–3(d) show the MFM images of the recording tracks at a linear density of 5000 fr/mm. The head widths are 2, 1, 0.75, and 0.5 μm , respectively. For all the four heads, the on-track portion of the transitions are well defined. The transitions near the track edges, however, become much more irregular than that at low densities as shown in Fig. 2. Such irregularity near the track edges becomes more critical

FIG. 3. MFM images of isolated tracks at linear density of 5000 fr/mm. The widths of the recording heads are: (a) 2 μm , (b) 1 μm , (c) 0.75 μm , and (d) 0.5 μm .

FIG. 4. MFM images of isolated tracks at linear density of 7000 fr/mm. The widths of the recording heads are: (a) 2 μm , (b) 1 μm , (c) 0.75 μm , and (d) 0.5 μm .

for the narrower tracks. For the 0.5- μm -wide track, the spatial scale of the irregularity is comparable to a significant portion of the track width. The transition fluctuations near the track edges result in effective track width reduction which shows as a form of partial erasure in spin-stand recording measurement.⁴ The edge transition fluctuations are likely to be caused by the relatively poor head field gradient near the track edges. The presence of any pole tip corner saturation, which could be the situation here, will worsen this effect.

Figures 4(a)–4(d) show the MFM images of the recording tracks at a higher linear recording density: 7000 fr/mm. At this density, for the 2 μm track, the intertransition percolation near the track edges becomes much more pronounced as shown in Fig. 4(a), while the intertransition percolation for the on-track portion is much less severe than that near the track edges. For the 1, 0.75, and 0.5 μm tracks, the percolation has extended from the track edges into significant portion of the entire track. In particular, for the 0.5- μm -wide track, percolation has caused complete self erasure of some of the transitions.

The above MFM images clearly demonstrate that the track edge percolation occurs at lower recording densities than the on-track percolation. For head widths in the near-micron or submicron range, the recording properties near the track edge become dominant. It is likely that the severe track

FIG. 5. The cross track signal power profiles of three tracks recorded with the 1 μm head at 2000, 3500, 5000 fr/mm linear densities.

edge percolation at high recording densities for the narrow track heads is closely related to the head saturation at the pole tip corners. Since the heads are trimmed from wide track heads, the flux to the pole tips must be in excess. In practice, it is believed that pole tip corner saturation always occurs and has been demonstrated by various head field modeling.⁵ Therefore, high moment write heads are necessary for high-density narrow track recording to ensure good field gradient at track edges.

C. Isolated track width and dc erase track width measurement

Using a technique similar to Ref. 6, we have measured the track widths for the trimmed heads at different densities. First, a series of single isolated tracks were recorded on a dc erased disk. Then the cross track signal power profiles were calculated from MFM images of these tracks. The track width is defined as the width of the region where the signal power is above half of the on-track amplitude. Figure 5 shows the obtained cross track profiles of 1 μm head recorded tracks. The recording densities are 2000, 3500, and 5000 fr/mm, respectively. The on-track signals are normalized to the same magnitude so that the track widths at different densities can be compared. The track widths measure 0.62, 0.58, and 0.50 μm for 2000, 3500, and 5000 fr/mm, respectively. As the recording density increases, the track width decreases.

Figure 6 summarizes the isolated track widths and dc erase track widths for the four trimmed narrow track heads. The linear curves indicate similar side writing characteristics of the four heads. The side writing is more related to the gap length and pole geometry rather than the pole width. For all

FIG. 6. The track width as a function of head width. The tracks are recorded at: 2000, 3500, and 5000 fr/mm. The dc erase track width is also shown. As recording density increases, track width decreases.

heads, similar track width reduction at high recording density is observed. The difference between the isolated track width and dc erase track width approximately equals twice the edge erase band. For these narrow heads, the dc erase track width is about 0.6 μm greater than the isolated track width which gives an erase band width of 0.3 μm . To further reduce the erase band and increase track packing density, it is also desirable to use high moment heads for generating high gradient head fields.

IV. CONCLUSIONS

We have studied the write properties of a series of very narrow thin-film heads with track widths ranging from 2 to 0.5 μm . We have experimentally shown 1- μm -deep pole trimming is sufficient to suppress the interference of the side fringing fields from the etched shoulders. It is found that track edge percolation occurs at lower densities than on-track intertransition percolation. Track edge percolation causes track edge fluctuations and effective track width reduction. As the track width is reduced to the near-micron or submicron ranges, the track edges become dominant portions of the track and consequently cause severe degradation of the recording tracks. Track edge percolation is caused by poor edge field gradients and is possibly enhanced by pole tip corner saturation. In order to achieve high-density narrow track recording, high moment heads become necessary.

Magnetic force microscopy images of ultrahigh-density bit patterns recorded on high-coercivity longitudinal and perpendicular thin-film media

Xing Song, John Sivertsen, and Jack Judy^{a)}

The Center for Micromagnetics and Information Technologies (MINT), Department of Chemical Engineering and Materials Science, University of Minnesota, MPLS, Minnesota 55455

Magnetic bit patterns recorded on high-coercivity longitudinal thin-film media (L1: $H_c=2500$ Oe, L2: 2850 Oe), and perpendicular thin-film media (P1: $H_c=2830$ Oe, P2: $H_c=3780$ Oe) were investigated using magnetic force microscope (MFM). For the longitudinal media, insufficient writing is responsible for limiting the detectable density. By reducing the head fly height from 3 to 2 microinches, the maximum detectable density of L1 is increased from 7000 to 10 500 fr/mm. At this density the well-defined track edge disappears and a complete bit collapse occurs as the bit length becomes much smaller than the average domain size observed in the dc-saturation remanent state. In the case of perpendicular media, contact recording provides sufficient writing and a well-defined track edge at densities above 10 000 fr/mm for both media. A maximum detectable density about 12 000 fr/mm is obtained in both media. At higher recording densities, domain refinement takes place but magnetic interactions within the track also cause the formation of large domains which eventually destroys the bit periodicity. © 1996 American Institute of Physics. [S0021-8979(96)08108-5]

I. INTRODUCTION

In order to achieve an ultrahigh recording density of 10 Gbits/in.², longitudinal media should have high coercivity (2500–3500 Oe) and low remanent magnetization-thickness product (0.5–1.0 memu/cm²).¹ Furthermore, it has been suggested that a possible way to realize even higher areal densities is to utilize perpendicular magnetic recording media.^{2,3} Some magnetic force microscopy (MFM) studies on thin-film recording media with coercivities below 2500 Oe have been reported.^{4,5} The purpose of this paper is to compare MFM images of ultrahigh-density bit patterns recorded on high-coercivity longitudinal and perpendicular thin-film media and investigate the effects of coercivity, remanent magnetization-thickness product, average domain size, head fly height, and formation of large domains on the recorded patterns.

II. EXPERIMENT

The two longitudinal media used in this experiment are CoCrPt/Cr thin films with different coercivities and remanent magnetization-thickness products: L1, $H_c=2500$ Oe, $Mr\delta=0.65$ memu/cm²; L2, $H_c=2850$ Oe, $Mr\delta=0.55$ memu/cm². The two perpendicular media with 7- μ m-thick NiFe underlayer used in this experiment are: P1, a 550 Å single-layer CoCrTaPt film with $H_c=2830$ Oe; P2, a multilayer 20×(7.5 Å Pd/3.5 Å Co) film with $H_c=3781$ Oe. An air-bearing spin stand tester was used for the recording measurements. The media were erased to dc-saturation remanent state before recording. For the longitudinal media, recording was done using an FeTaN head with $B_s\sim 18$ kG, gap length ~ 0.29 μ m, and track width ~ 5.30 μ m at a fly height of ~ 3 microinches unless otherwise stated. For the perpendicular media, contact recording was realized using a CoNbZr single-pole head with track width ~ 5.27 μ m. Magnetic

force microscope images of the recorded bit patterns were obtained using a Nanoscope III in a “tapping-lift” mode with a CoCrTa/Cr-coated tip magnetized in the vertical direction.

III. RESULTS AND DISCUSSION

A. Recording measurements

Figure 1 shows the roll-off curves of the four media. The reproduced voltages for the longitudinal media are almost constant below 4000 fr/mm and drop sharply above 4500 fr/mm. The signals for the perpendicular media start to drop above 3000 fr/mm. A D_{50} of about 5000 fr/mm is obtained in all cases. Signal is undetectable above 7000 fr/mm for the longitudinal media, whereas second peaks around 10 000 fr/mm are obtained for the two perpendicular media.

Noise measurements indicate a smaller integrated medium noise for L2 and P2 compared with L1 and P1, respectively (not shown). It is also observed that P2 suffers from significant larger PW_{50} than P1 (P1: 17.7 microinches, P2: 32.3 microinches).

FIG. 1. Reproduced voltage vs linear density of the four media.

^{a)}Department of Electrical Engineering.

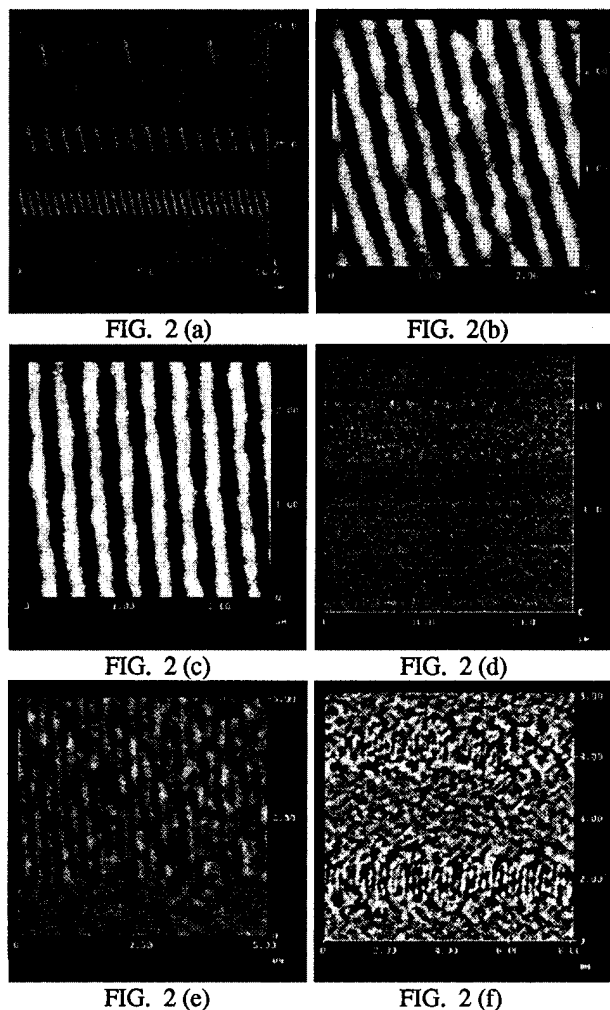

FIG. 2. MFM images of bit patterns recorded on medium L1 and L2. (a) L1: 100, 500, and 1000 fr/mm. (b) L1: 7000 fr/mm. (c) L2: 7000 fr/mm. (d) L2: 8000 fr/mm (top) and 9000 fr/mm (bottom). (e) L2: 8000 fr/mm [a zoom-in image of the top portion of (d)]. (f) L1: 9500 fr/mm (bottom) and 10 500 fr/mm (top), recorded at a fly height of 2 microinches.

B. MFM images of high-coercivity longitudinal media

Figure 2 shows tracks recorded on L1 and L2 at different densities. The same tip was used to obtain these images. The tip lift scan height was set at 40 nm. The general features of the recorded bit patterns of the two longitudinal media are similar at low densities. Figure 2(a) shows the MFM images of bit patterns recorded on L1 at three different low densities. These recorded tracks exhibit sharp bit transitions and well-defined track edges.

The average domain size observed in the dc-erased background of these media is ~ 270 nm for L1 and ~ 200 nm for L2. Domains of the same size exist within the recorded bits in each medium. Smaller domains are indication of smaller magnetic exchange interaction and the smaller exchange coupling within L2 explains its smaller integrated medium noise observed in the recording measurement.

As the recording density increases and the bit length approaches or becomes smaller than these average domain sizes, zig-zag transitions become more significant and perco-

lation starts to take place. Figures 2(b) and 2(c) show 7000 fr/mm tracks recorded on these media. L2 suffers less from bit transition degradation and exhibits a larger maximum detectable density of 8000 fr/mm [Fig. 2(e)] compared with 7000 fr/mm of L1 because of the lower $Mr\delta$ and smaller domain size in L2. Figure 2(d) shows two tracks recorded at 8000 and 9000 fr/mm on L2. Figure 2(e) is a zoom-in image around the 8000 fr/mm track. The 9000 fr/mm track is not distinguishable from dc-erased background even by a closer inspection with a higher magnification and smaller tip-to-sample separation (not shown).

In order to improve the magnetic interaction between the head and the medium, bit patterns were recorded on L1 using a head with track width of $2\ \mu\text{m}$ at a lower fly height of 2 microinches. Figure 2(f) shows the tracks with linear densities of 9500 and 10 500 fr/mm recorded on L1. It is clear that a much higher detectable density on L1 is achieved as the head fly height is reduced. Similar improvement of the detectable density in L2 is expected.

At these ultrahigh densities the effective track width is reduced from 2 to $1.3\ \mu\text{m}$ and well-defined track edge no longer exists. Magnetic interaction between the recorded track and the dc-erased background causes the formation of some magnetic domains slightly larger than the average size at the track edges and severe percolation takes place within the tracks. As the write density increases further, bit pattern collapse completely because of a bit length much smaller than the average domain size and can not be resolved.

C. MFM images of high-coercivity perpendicular media

Figure 3 shows several tracks recorded on P1 and P2 at different densities. All images were obtained using the same tip with the tip lift scan height set at 80 nm. Writing is sufficient for these high-coercivity media due to a contact recording mode and a reduced demagnetizing field at high density (indicated by straight track edges). A maximum detectable density of 12 000 fr/mm is obtained on both media.

As mentioned in Sec. III A, recording measurements indicate that P2 has a smaller integrated medium noise and a larger PW_{50} than P1. The MFM images shown in Fig. 3. provide insight understanding of these results. As shown in Fig. 3(a), magnetic domains having ~ 250 nm in average size are clearly observed in both the dc-erased background and within the bits for P1. In the case of P2 shown in Fig. 3(c), magnetic domains can be hardly seen although the frequency scale of the two images is the same (z range: 100 Hz). By reducing the frequency scale, magnetic domains with the size ~ 130 nm can be resolved (not shown). It is observed that zig-zag transitions are present within the track on P2 at density as low as 1000 fr/mm, which develop into magnetic interference at intermediate density as shown in Fig. 3(d). From the recording results and these observations, it is concluded that P2 has a smaller integrated medium noise because of a smaller exchange coupling (indicated by its smaller magnetic domain size) and the magnetic irregularities present at bit transitions account for its large PW_{50} detected in the recording measurement.

Figure 3(e) shows a 12 000 fr/mm track on P1. A domain refinement phenomenon is observed. After applying and re-

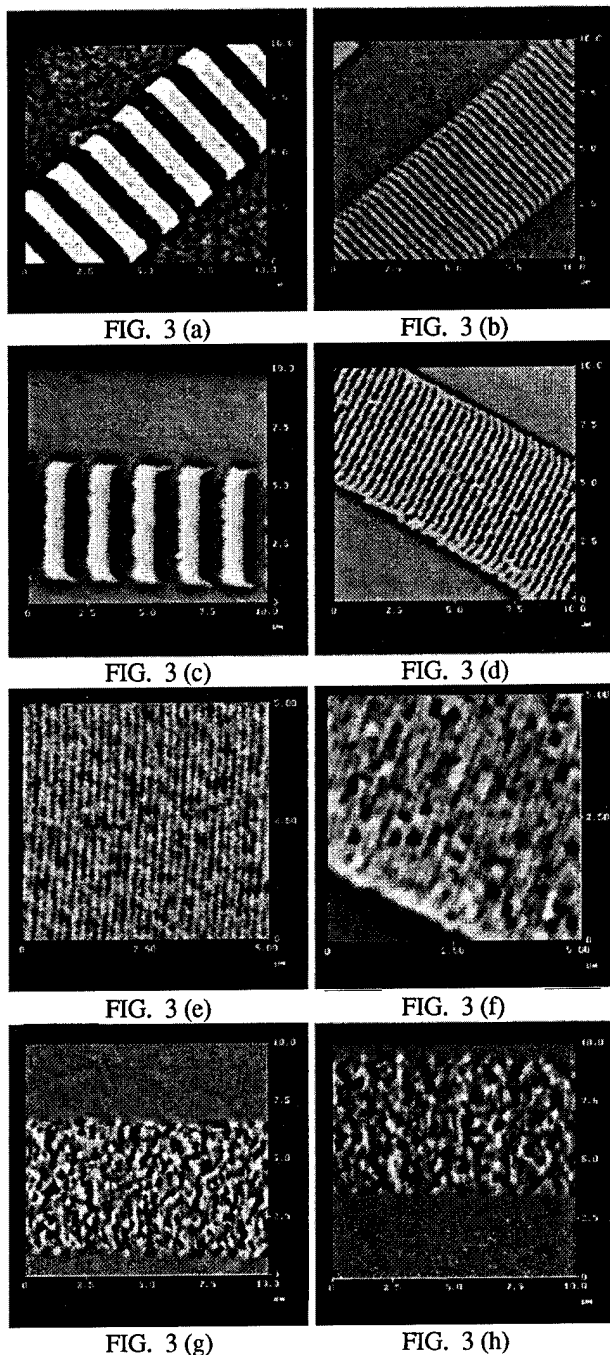

FIG. 3. MFM images of bit patterns recorded on medium P1 and P2. (a), (b) P1: 1000 and 5000 fr/mm. (c), (d) P2: 1000 fr/mm and 5000 fr/mm. (e) P1: 12 000 fr/mm. (f), (g), (h) P2: 11 000, 12 000, 14 000 fr/mm.

moving the high-frequency write field, domains with original size of ~ 250 nm in the dc-erased state break into smaller domains of ~ 80 nm. At some locations along the bits, local magnetic domains reverse their polarities with respect to

their neighbors' and these magnetization discontinuities lead to signal loss at this density. Figure 3(f) shows a 11 000 fr/mm track recorded on P2. Magnetic domains crossing several bit lengths distribute randomly within the track although individual bits can still be resolved indicating the domain refinement phenomenon. The formation of these domains are caused by magnetic interactions within the track after the high-frequency write signal is removed. Figures 3(g) and 3(h) show tracks recorded on P2 at even higher densities. 12 000 and 14 000 fr/mm. The large domains formed within the track grow in number and in size as the write density increases. Signal peak at 166 nm wave length corresponding to 12 000 fr/mm write density is observed in the spatial frequency domain of Fig. 3(g). As the write density increases to 14 000 fr/mm, domains of 200–700 nm in size form within the track and no signal peak corresponding to this density can be resolved in the frequency domain.

IV. CONCLUSIONS

(1) Ultrahigh-density bit patterns high-coercivity of 10 500 and 12 000 fr/mm are resolved in MFM images of longitudinal and perpendicular media, respectively. Smaller integrated medium noise is obtained from media with smaller average domain size in both kinds of media.

(2) In the longitudinal recording, well-defined track edge disappears and severe percolation destroys the signal written within the track at ultrahigh densities. The detectability of the recorded tracks is dominantly limited by insufficient writing and average domain size observed in the dc-saturation remanent state of the media.

(3) In the perpendicular recording, because of a contact recording mode, the writing is sufficient even for a medium with coercivity as high as 3780 Oe. At ultrahigh densities, domain refinement takes place and local magnetization reversal leads to a reduced signal to noise ratio. Formation of large domains within the track ultimately destroys the signal.

(4) A less severe zig-zag transition is observed in the medium with a smaller $Mr\delta$ in the longitudinal recording. The zig-zag transition and magnetic interference observed in P2 contribute to a large PW_{50} .

The effect of physical structure on δI curves of longitudinal thin film (abstract)

N. S. Walmsley, A. Hart, and D. A. Parker

Department of Mathematics and Statistics, University of Central Lancashire, Preston, Lancashire, PR1 2HE, United Kingdom

C. Dean and R. W. Chantrell

Department of Physics, University of Keele, Keele, Staffordshire, ST5 5BG, United Kingdom

Conventionally, the simulation of thin films has been carried out using an HCP structure to represent its physical structure. Such an idealized structure has been shown to overestimate the effect of interparticle coupling by using an homogeneous exchange coupling scheme.¹ A more realistic approach to represent physical structure has been undertaken by generating a system of grains which lie on a radially isotropic structure and have a nonuniform volume distribution. Interaction effects can be shown by computing δI curves formed through the comparison of the remanence curves using the Wohlfarth relation. To generate an isothermal remanence curve (IRM), a realistic ac erased state is necessary which has been carried out by using a simulated annealing technique.² A comparison has been made to determine the effect of physical structure on the bulk properties by computing hysteresis loops, remanence curves, and δI curves. To reduce statistical error these have been averaged over four different sets of easy axes. The loops indicate that an irregular physical structure leads to an increase in the coercivity and decrease in the squareness. The dc-demagnetization curves show an increase in remanent coercivity; this can be attributed to the random physical structure decreasing the size of magnetically correlated regions within the microstructure. The effect of the physical microstructure on the δI curves will be discussed in full in the paper. © 1996 American Institute of Physics. [S0021-8979(96)45708-3]

Mary Doerner

IBM Storage Systems Division, 5600 Cottle Road, San Jose, California 95193

The effects of medium inhomogeneities in microstructure and exchange configuration are studied by using micromagnetic simulation. Two types of media are studied: one has a uniform bicrystal structure and another has a partial bicrystal structure with 20% random nonbicrystal sites. The comparison of magnetic (M - H loops) and recording properties (transition profiles and noise) for these two types of media are made under two cases with homogeneous or inhomogeneous intergranular exchange coupling. It is found that the introduction of random nonbicrystal sites reduces the medium noise in the case with homogeneous intergranular exchange, while medium noise is barely affected in the case with inhomogeneous intergranular exchange. © 1996 American Institute of Physics. I. INTRODUCTION

Current high-density recording utilizes polycrystalline thin films as recording media. It is important to understand the medium noise mechanism and its dependence on microstructure. Suitable epitaxial growth conditions can give rise to bicrystal microstructure, where a polycrystalline thin film consists of bicrystal clusters.^{1,2} Each bicrystal cluster consists of subcrystallites that possess two possible orthogonal easy axis. Due to their unique microstructure, bicrystal media have been studied, and proposed as possible candidate media for future ultrahigh density recording.^{3,4} Experimental evidence (e.g., x-ray diffraction and TEM images) indicates that there exist nonbicrystal sites in a bicrystal thin film. It is the purpose of this work to further explore (following the work of Ref. 4) the implication of such inhomogeneity on medium magnetic and recording properties by using micromagnetic simulation.

II. MODELING

In this study, we use a 256×128 planar hexagonal array to model the actual medium. Each hexagon corresponds to a Co alloy subcrystallite which is assumed to be single domain and to possess a uniaxial c axis. A grain, which can be either bicrystal or nonbicrystal, is represented by using a cluster of a hexagon subcrystallite and its six nearest neighbors. The height to diameter aspect ratio of a single hexagon subcrystallite is 3:1 in order to keep the aspect ratio of the grains to be unity ($\delta/D=1$). The diameter of bicrystal cluster is assumed to be 18 nm. Within a bicrystal grain, the c axis of subcrystallites are along two mutually orthogonal orientations in the film plane. Among bicrystal grains, their c axis are randomly oriented. In an individual nonbicrystal grain, all subcrystallites have the same direction of c axes. The c axis are 3D randomly oriented among nonbicrystal grains. The modeling of bicrystal and nonbicrystal clusters is illustrated in Fig. 1.

The magnetostatic interaction is described by a scaled constant $h_m = M_s/H_k$, where M_s is the saturation magnetization and $H_k = 2K/M_s$ is the anisotropy field. A fixed magni-

tude is assumed for each subcrystallite's anisotropy field H_k . In this article, an intrinsic anisotropy energy constant $K \sim 1.5 \times 10^6$ erg/cc and saturation magnetization $M_s \sim 360$ emu/cc are utilized throughout the study, which yields $h_m \sim 0.04$. The exchange coupling between neighboring subcrystallites is described by the normalized parameter $h_e = A^*/KD^2$, where A^* is the effective intergranular exchange constant. Two different exchange constants, h_e^{in} and h_e^{out} were used. The term h_e^{in} describes the coupling between the Co alloy subcrystallites within a grain, while h_e^{out} gives the coupling between neighboring grains, as shown in Fig. 1. It is assumed that bicrystal grains and nonbicrystal grains have similar exchange features.

The dynamics of magnetization reversal is solved by using the Landau-Lifshitz equations.⁵ The hysteresis and recording dynamics are simulated. The following recording parameters are used: head medium spacing $d' + \delta/2 = 25$ nm and recording gap $g = 0.35$ μm . The playback signals are obtained by convolving the recorded magnetization transition profile with the playback magnetoresistance (MR) head field, where the Potter approximation⁶ is used. The shield-to-shield spacing G for the MR head is 0.2 μm . The width of the MR element, which defines the playback track width, is 0.5 μm .

FIG. 1. Modeling of a subgrain cluster, where seven subcrystalline grains are utilized for computation use Ref. 3. The cluster on the left corresponds to a bicrystal cluster. The cluster on the right is a nonbicrystal cluster.

TABLE I. Summary of the simulated media with different microstructures and exchange configurations.

	Microstructure	h_{in}	h_{out}
Type A (Case I)	Uniform bicrystal	0.16	0.16
Type B (Case I)	20% Random nonbicrystal	0.16	0.16
Type A (Case II)	Uniform bicrystal	0.31	0.056
Type B (Case II)	20% Random nonbicrystal	0.31	0.056

The MR element thickness is assumed to be much smaller than G .

III. RESULTS AND DISCUSSIONS

Two types of media are investigated. Type A has a uniform bicrystal structure where all grains possess bicrystal microstructure. Type B has a partial bicrystal structure where there are 20% random nonbicrystal sites. We further divide our studies into two cases according to the characteristics of exchange interaction. In case I, uniform intergranular exchange is used. In case II, inhomogeneous exchange interactions are used, where a strong exchange interaction within the bicrystal cluster and a relatively weak exchange between the bicrystal clusters are chosen. The microstructures and micromagnetic parameters used in the simulation are summarized in Table I. The terms h_{in} and h_{out} are chosen to keep the coercivity of type B medium in case I and II around 2500 Oe.

The comparisons of simulated M - H loops of type A and type B media for case I and case II are plotted in Figs. 2(a) and 2(b), respectively. The remanent squareness and coercivity are listed in Table II. In case I, type A medium has a coercivity of 2440 Oe, very close to the coercivity of type B, which is 2470 Oe. Type B medium has slightly smaller re-

TABLE II. The simulated magnetic and recording properties.

	S	H_c (Oe)	a/D	SNR
Type A (Case I)	0.87	2440	1.04	25.6
Type B (Case I)	0.82	2470	1.14	27.6
Type A (Case II)	0.88	2240	0.89	31.5
Type B (Case II)	0.81	2510	0.93	31.8

manence squareness S of 0.82, compared with type A medium with $S \sim 0.87$. In case II, type A medium has a coercivity of 2240 Oe and $S \sim 0.88$. The introduction of 20% random nonbicrystal sites increases the coercivity of type B medium to 2510 Oe and reduces its S to 0.81.

The transition profiles and noise distributions of the type A and type B media are simulated and shown in Fig. 3(a) for case I and in Fig. 3(b) for case II. The simulated transition parameters and signal-to-noise ratio (SNR) [at a recording density of 100 kfc] are listed in Table II. In case I, the simulated transition parameter a/D of type A medium is ~ 1.04 . The transition of type B medium is broadened with larger transition parameter $a/D \sim 1.14$. Compared with the type A medium, the transition noise of type B is reduced due to the existence of random nonbicrystal sites, as shown in Fig. 3(a). The type B medium yields approximately 2 dB better SNR than type A. In case II, the transition profile of type B with $a/D \sim 0.93$ is slightly broadened from the type A medium with $a/D \sim 0.89$, even though type B has a larger coercivity than type A. The introduction of 20% random nonbicrystal sites has little effect on medium noise in case II. In this case, the type B medium has approximately the same noise level as type A, as seen from Fig. 3(b).

By comparing case I and II, it is found that media in case II generally have sharper transitions and lower noise than in case I. The physical origins lie in two aspects. First of all,

FIG. 2. Comparisons of M - H loops of type A (solid) and type B media (dashed), (a) with homogeneous exchange interactions (case I), (b) with inhomogeneous exchange interactions (case II).

FIG. 3. Comparisons of transition profiles and noise of type A (solid) and type B (dotted) media, (a) for case I with $h_{in}=h_{out}=0.16$, (b) for case II with $h_{in}=0.31$ and $h_{out}=0.056$.

media in case II have smaller h_{out} , which governs the exchange interaction between clusters. This will result in a better decoupling between clusters, which will lower the transition noise and reduce the transition width. Furthermore, as discussed in Ref. 4, another important physical phenomena is the fluctuation of the "effective" anisotropy energy constant of a magnetic grain, which consists of tightly coupled sub-crystallites. In the "tightly coupling" case, the effective anisotropy energy constant can be approximated by $K_{\text{eff}} = (1 - A_{\parallel}/A_{\perp}) / (1 + A_{\parallel}/A_{\perp}) \cdot K$, where A_{\parallel}/A_{\perp} is the relative area percentage ratio of the mutually orthogonal sub-crystallite axes and K is the intrinsic anisotropy. The variation of the effective H_k from grain to grain will lower the medium noise further by reducing the effect of exchange coupling between the neighboring grains.⁷ The nonbicrystal grain in the type B medium will possess an effective anisotropy $K_{\text{eff}} \approx K$, which explains the increase of coercivity for the type B medium in case II. In addition, due to the existing effective H_k fluctuation, the randomness induced by the 20% nonbicrystal sites will have little effect on medium noise. However, the situation is different for case I, where the tight coupling approximation is no longer valid due to the homogeneous exchange coupling. In this case, the 20% random nonbicrystal grains that exist in the type B medium will induce noticeable new randomness that will reduce the effect of exchange coupling and lower the noise.

It is still unclear which case of I and II is closer to the medium in reality. Further experimental and theoretical works are needed to clarify this complication. There are two main mechanisms that can cause the weakening of exchange interactions between the grains, either the existence of voids or significant Cr segregation at the grain boundary. In some most recent CoPtCr bicrystal media, TEM images reveal no

clear voids between the grain boundaries.⁴ Recently, electron spectroscopic imaging analysis of the compositional inhomogeneity in CoTaCr indicates Cr segregation at the grain boundaries and intra grains.⁸

IV. CONCLUSIONS

The effects of inhomogeneities in microstructure and exchange configuration are studied by using micromagnetic simulation. The introduction of partial random nonbicrystal sites reduces the medium noise in the case with homogeneous intergranular exchange. It has little effect on medium noise in the case with inhomogeneous intergranular exchange.

Multilevel master equation for bicrystal clusters

I. Klik and Y. D. Yao

Institute of Physics, Academia Sinica, NanKang, Taipei, Taiwan, Republic of China

C. R. Chang

Department of Physics, National Taiwan University, Taipei, Taiwan, Republic of China

A bicrystal film is modeled as an ensemble of clusters of four particles which interact via short-range exchange coupling. Their easy axes are oriented pairwise along two randomly chosen orthogonal directions and the relaxational dynamics of the resultant clusters are described in terms of a multilevel master equation. The randomly deposited bicrystal film is compared with a randomly deposited film of uniaxial clusters. The relaxational properties of the entire array are determined by the easy axes arrangement and by the nature of coupling within the cluster. In particular, for ferromagnetic coupling the occurrence probability of fully magnetized bicrystal cluster states is high and we propose that in conjunction with the highly isotropic coercivity this property leads to a sharp transition between film regions magnetized in opposite directions. © 1996 American Institute of Physics. [S0021-8979(96)08208-1]

Bicrystal films have recently attracted considerable attention,¹⁻³ both from the point of view of material science^{4,5} and of applications to information storage.^{6,7} They combine the beneficial properties of highly oriented and isotropic films, being distinguished, in particular, by coercivity squareness which approaches unity⁶ and by low noise levels⁷ at high recording density. It was suggested that these desirable qualities result from the fourfold symmetry of the film microstructure: A nanocrystalline film, e.g., the Cr(100)/Co-alloy(11 $\bar{2}$ 0) epitaxial structure, with randomly oriented bicrystal clusters shows a better recording performance than an ordered bicrystal film.² Both the (oriented) bicrystal⁶ and the (globally disordered) nanocrystalline films² have been proposed, at least micromagnetically, as suitable media for high-density recording up to 10 Gbits/in.², yet their thermal stability has not been, to date, studied. Here we use previously developed multilevel master equation formalism⁸ to analyze the relaxation properties of locally coupled four particle clusters. We find that the relaxational properties of the cluster array are determined by the arrangement of easy axes within the cluster and by the nature of the local coupling: For negative exchange (ferromagnetic) coupling the occurrence probability of fully magnetized cluster configurations is found to be very high and insensitive to temperature. We expect these properties to lead to a sharp transition between the regions magnetized in opposite directions.

We assume that each configuration of the N locally interacting constituent particles has a definite arrangement of easy axes; here we set $N=4$ and adopt the biaxial symmetry shown in Fig. 1. Also shown there is a cluster of four aligned particles whose properties and stability we shall compare with the biaxial model. In either case the clusters are deposited in the $x-y$ plane and their orientation with respect to the in-plane applied field $\mathbf{H}=(H,0,0)$ is random. For simplicity of calculation (see below) we further assume that all constituent particles are identical. Parametrizing their magnetization vectors as $\mathbf{M}_i=M_s(\cos \phi_i, \sin \phi_i, 0)$, $\phi \in (0, 2\pi)$ and M_s is the saturation magnetization, we obtain the expression

$$E = KV \sum_{i=1}^2 [\sin^2(\phi_{2i-1} - \beta) + \cos^2(\phi_{2i} - \beta)] - V \sum_{i=1}^4 \mathbf{M}_i \cdot \mathbf{H} + E_{\text{int}} \quad (1)$$

for the total energy of the biaxial cluster, and similarly also for the uniaxial one whose anisotropy energy is given by the sum $KV \sum_i^4 \sin^2(\phi_i - \beta)$. The random inclination angle $\beta \in (0, \pi/2)$ is defined in the sketch of Fig. 1; K is anisotropy constant, V activation volume, and M_s saturation magnetization. In the absence of mutual interactions the two species of constituent particles have identical nucleation fields, $H_n(\beta)/H_n(0) = [\cos^{2/3} \beta + \sin^{2/3} \beta]^{-3/2}$, $H_n(0) = 2K/M_s$, easily obtained by solving the coupled equations $\partial E / \partial \phi_i = \partial^2 E / \partial \phi_i^2 = 0$. We assume that local interactions within the clusters are exchange dominated² and in order to avoid a proliferation of adjustable parameters we set

$$E_{\text{int}} = \rho \sum_{i \neq j=1}^4 \mathbf{M}_i \cdot \mathbf{M}_j \quad (2)$$

FIG. 1. The two species of four particle clusters considered in text. Easy axes of the constituent particles are depicted by doubleheaded arrows; the upper left cluster thus has biaxial and the lower right uniaxial symmetry. The inclination angle β and the orientation of the applied field \mathbf{H} correspond to Eq. (1).

FIG. 2. The angular dependence of coercivity for the biaxial (solid lines) and uniaxial (dashed lines) clusters. Coupling strength $\rho M_s^2/KV = -10^{-2}$ (uppermost curves), 0 (middle curves) and 10^{-2} (lowermost curves).

so that the detailed cluster geometry becomes in this approximation irrelevant. The (global) weak interactions between separate clusters may be modeled within the mean field theory,⁹ where $\mathbf{H} \rightarrow \mathbf{H}_{\text{eff}} = \mathbf{H} + \alpha \langle \mathbf{M} \rangle$ in Eq. (1), $\langle \mathbf{M} \rangle$ is the instantaneous magnetization of the entire array, and α a phenomenological parameter. By assumption the mean field $\alpha \langle \mathbf{M} \rangle$ is weaker than the interaction field (2) and in this paper, where we do not carry out averaging over the inclination angle β , we disregard it altogether. If included, the mean field will slightly deform and shift⁹ the resultant hysteresis loops without introducing any qualitatively new features into the model.

It has recently been shown⁸ that the thermally activated evolution of an array of interacting single-domain particles, as represented here by Eqs. (1) and (2), may be described by the master equation

$$\frac{dn_i}{dt} = - \sum_{j=1}^{\mathcal{N}} R_{ij} n_j \quad (3)$$

for the probabilities n_i that the $\mathcal{N} \leq 2^N$ distinct metastable minima of the total energy (1) are occupied, i.e., that the cluster finds itself in a particular magnetic configuration. The elements R_{ij} are the rates of thermally activated transitions between these metastable minima (configurations). For arbitrary coupling strength ρ they are expressed¹⁰ in terms of the minima and saddle point energies of Eq. (1). This poses, however, a formidable extremal problem¹¹ and for this reason we adopt here the weak coupling limit⁸ in which E_{int} is treated as a small perturbation of the total energy (1). This limit excludes simultaneous reversals of two or more particles within the cluster and the admissible single particle reversals take place in a local field defined by the magnetizations of the partner (nonreversing) particles which are assumed to be frozen at their respective local energy minima in each of the \mathcal{N} possible metastable configurations. Each particle has a nonzero reversal probability in every one of the \mathcal{N} possible configuration of the entire cluster and the tran-

sition elements R_{ij} are then expressed as linear combinations of the $N \times \mathcal{N}$ single particle relaxation rates. For not too large \mathcal{N} the master Eq. (3) is easily solved numerically using the stable backward Euler method.¹²

The biaxial cluster of Fig. 1 has $\mathcal{N} = 10$ distinct metastable configurations whereas for the uniaxial cluster $\mathcal{N} = 5$. In considering the stability of the cluster we could, in principle, analyze the occurrence probability $n_i(t)$ of every possible metastable configuration but it is more convenient to define the probabilities $p_n(t)$, $n = 0, 1$, and 2 , that either n or $4-n$, particles have reversed by the time t . Note that for an isolated particle $p_0(t) \equiv 1$ at all times since the particle either did or did not reverse and no third possibility exists.

At a given inclination angle β we subject both cluster species to a periodic applied field $H(t) = H_n(0) \cos 2\pi f t$ of frequency $f = 0.5$ Hz and calculate the major hysteresis loop. In our model calculation we set $KV/k_B T = 42$ and for the prefactor of thermal decay rate^{8,10,11} we choose the value $f_0 = e^{25}$ Hz $\approx 7.2 \times 10^{10}$ Hz. The chosen temperature is relatively very high, corresponding to an isolated particle lifetime of about nine months. The angular dependence of the coercivity $H_c(\beta, \rho)$ is primarily determined by the axes orientation within the cluster while the influence of interactions between the constituent particles is relatively minor. The variation of coercivity with orientation, however, is significantly smaller for the more isotropic biaxial model than for the uniaxial model and this, in particular, implies a smaller dispersion of single particle switching events in a randomly deposited sample (see Fig. 2).

Even though interparticle interactions have, in the present model, only minor influence on coercivity, they do *significantly affect* the stability of partially magnetized clusters in which one (or three) resp. two particles have reversed with probabilities $p_1(t)$ resp. $p_2(t)$ by the time t . According to Eq. (2) positive exchange interactions ($\rho > 0$) favor the formation of configurations with antiparallel alignment of single particle magnetization vectors, i.e., they stabilize partially magnetized clusters. Negative coupling, on the other hand, inhibits the formation of such configurations and increases the stability of fully magnetized states in which all or no particles have reversed with probability $p_0(t)$. In Fig. 3 we plot, for selected values of β , the nonequilibrium magnetization $M[H(t)]$ of the biaxial cluster together with the corresponding probabilities $p_2[H(t)]$. The figure shows that even small *negative* coupling significantly decreases the probability p_2 (and similarly also for p_1) that the cluster will find itself in one of the partially demagnetized configurations anytime during the hysteresis process. The effect is even more pronounced at lower temperatures. In particular, for $KV/k_B T > 46$ and $\rho M_s^2/KV = -10^{-2}$, we obtain $p_0(t) \approx 1$ at all times and the partially demagnetized states become all but absent from the hysteresis process. At the same time, the switching field distribution $\chi[H(t)] = \partial M[H(t)] / \partial H(t)$ becomes more sharply peaked as the intermediate states are suppressed. Similar conclusions may be also reached about the thermal stability of uniaxial clusters; in this case, however, the probabilities $p_1(t)$ and $p_2(t)$ lack the striking isotropy displayed by the plots of Fig. 3.

In summary, we find that even very small negative (fer-

FIG. 3. The nonequilibrium magnetization $M(t)$ of the biaxial cluster measured along the applied field (solid lines) together with the probabilities $p_2(t)$. Inclination angle $\beta=5^\circ$ (leftmost curves), 9° , 14° , 18° , 22° , 31° , and 40° (rightmost curves). The magnetization curves are plotted for $\rho=0$, the probabilities plots are for $\rho M_s^2/KV=-10^{-2}$ (with plots inverted, $p_2 \rightarrow -p_2$, for clarity) and 10^{-2} . Note that the values of p_2 (here $\max p_2 \approx 0.08$ for $\rho < 0$ and $\max p_2 \approx 0.65$ for $\rho > 0$) are highly isotropic.

romagnetic) exchange forces significantly inhibit the formation of partially demagnetized configurations of four particle clusters for all technically relevant values of the ratio $KV/k_B T$. This finding is of interest to magnetic recording technology since the high probability of finding a fully magnetized cluster leads one to expect a sharp boundary between

film regions magnetized in opposite directions. This feature, moreover, is quite insensitive to the orientation of a biaxial cluster (see Fig. 3). This may be of benefit to manufacture of hard disks where uniaxial clusters have to be aligned with the tangential direction. Randomly oriented biaxial clusters form a highly homogeneous, stable recording medium whereas an array of randomly oriented uniaxial clusters is highly inhomogeneous, with a substantial fraction of the clusters likely to be found in one of the possible partially demagnetized states.

D. Weller

IBM Almaden Research Center, San Jose, California 95120-6099

The coercivity is one of the key parameters for defining a suitable magneto-optic recording material. In order to get insight into coercivity mechanisms we have studied the magnetization reversal processes by means of magneto-optic methods in CoPt alloy films. These films were prepared in UHV by coevaporation with a typical composition ratio of $\text{Co}_{28}\text{Pt}_{72}$ and show excellent perpendicular magnetic anisotropy at elevated substrate temperatures during deposition. STM and x-ray measurements reveal characteristic grain size of about 15–20 nm and dispersion of crystallite axis of the order of 0.5° , respectively, which varies only slightly with total film thicknesses of 5–50 nm. The magnetization reversal processes are investigated by using polar Kerr microscopy and were found to be dominated by domain formation and domain wall propagation. A micromagnetic model was developed which describes the film as an ensemble of single domain particles. The size of these single domain particles was chosen to be of the order of the average grain size. In the numerical simulation we include dipolar interaction and domain wall energy contribution. The comparison of the results of the simulation with the experimental results clearly points out that the microstructure is responsible for the magnetization reversal behavior. A thermal as well as thermally activated magnetization processes contribute to the reversal mechanism. The coercivity is predominantly determined by pinning on grain boundaries. © 1996 American Institute of Physics.

Grain morphology and magnetic properties of CoCrPt/Cr(Si,Ti) films sputtered at room temperature

G. Choe

Materials Research Corporation, Route 303, Orangeburg, New York 10962

CoCrPt films were deposited on Cr-Si and Cr-Ti underlayers at room temperature with variations in Si and Ti concentration. Magnetic properties including H_c and S^* were improved by Cr-Si and Cr-Ti underlayers. CoCrPt films deposited on a Cr-Si underlayer showed uniformly grown Co grains without large chains of grouped fine grains that were observed for the films deposited on a Cr underlayer, thus resulting in the increased S^* . The Cr-Ti films showed changes in crystallography with increasing Ti content and thus affected the growth texture of Co grains. It is suggested that high performance CoCrPt recording media can be fabricated at room temperature by modifying the Cr underlayer films. © 1996 American Institute of Physics. [S0021-8979(96)08308-8]

I. INTRODUCTION

High-density longitudinal recording media require low noise and high coercivity. Previous reports indicated that media noise could be significantly reduced by the decreased magnetic exchange coupling.¹⁻⁴ Several methods including voided Co alloy with thick Cr underlayer¹⁻³ or Cr segregated Co alloy⁴ are reported to be effective in achieving an exchange decoupling. Most previous studies to reduce media noise and enhance coercivity were performed using Co alloy thin films sputtered onto a heated substrate for the purpose of achieving a preferred orientation of c axis and also promoting Cr segregation. However, the heating prior to deposition may complicate the disk manufacturing process, since the aluminum substrate can be thermally distorted and the amorphous Ni-P can be crystallized. In the present study, grain morphology and magnetic properties of CoCrPt films sputtered on Cr-Si and Cr-Ti underlayer films at room temperature were investigated. This paper reports that alloying of the Cr underlayer controls the grain growth of CoCrPt films deposited without substrate heating and thus improves the magnetic properties of CoCrPt.

II. EXPERIMENTS

Co₆₈Cr₁₄Pt₁₈ thin films on a Cr underlayer were deposited onto glass substrates at room temperature by rf magnetron sputtering. The thicknesses of the Cr underlayer and CoCrPt layer were 1500 and 500 Å, respectively. The Cr layer was deposited at 5 mTorr of argon pressure, while the CoCrPt layer was deposited at 10 mTorr. The compositions of Si and Ti in the Cr layer were varied using Si and Ti chips placed on the Cr target and were analyzed by energy dispersive spectroscopy (EDS) using a transmission electron microscope (TEM). Magnetic properties including coercivity (H_c), magnetization (M_s), squareness (S), and coercive squareness (S^*) were measured using vibrating sample magnetometer (VSM) and microstructural characterization was performed by TEM using plane and cross-sectional observation. The crystallography was investigated using x-ray diffraction (XRD) with Cu $K\alpha$ radiation.

III. RESULTS AND DISCUSSION

Figure 1 shows plane-view TEM micrographs of CoCrPt films deposited on a Cr underlayer at different substrate temperatures. The CoCrPt films deposited at 200 °C exhibited Co grains separated from neighboring grains by void boundaries and the grain size was uniform. A magnetic coercivity (H_c) of 1880 Oe was observed with high coercive squareness (S^*) of 0.88. However, the CoCrPt films deposited without substrate heating showed remarkably different grain morphology from the films deposited with substrate heating, as shown in Fig. 1(b). The Co grain diameter ranged widely from 60 to 120 Å, and the fine grains were coupled in the shape of large chains. This effect possibly resulted in low S^* of 0.71 for the films deposited at room temperature, although H_c remained nearly constant at 1900 Oe due to the well isolated Co grains. Thus, in the present study, CoCrPt films were deposited on a Cr-Si or Cr-Ti underlayer that is expected to modify the morphology and/or crystallography of pure Cr to attempt to change the Co grain morphology and crystallography, thereby improving S^* .

Figure 2(a) shows the effect of a Cr-Si underlayer on the magnetic properties of CoCrPt films sputtered at room temperature as a function of increasing Si concentration. The CoCrPt films deposited on a Cr-Si underlayer showed higher H_c and S^* than the films deposited on a Cr underlayer. H_c increased linearly with increasing Si content and was maximized (2600 Oe) at 5.8 at. % Si, but slightly decreased with

FIG. 1. Plane view of TEM micrographs of CoCrPt films sputtered on a Cr underlayer at (a) 200 °C and (b) room temperature.

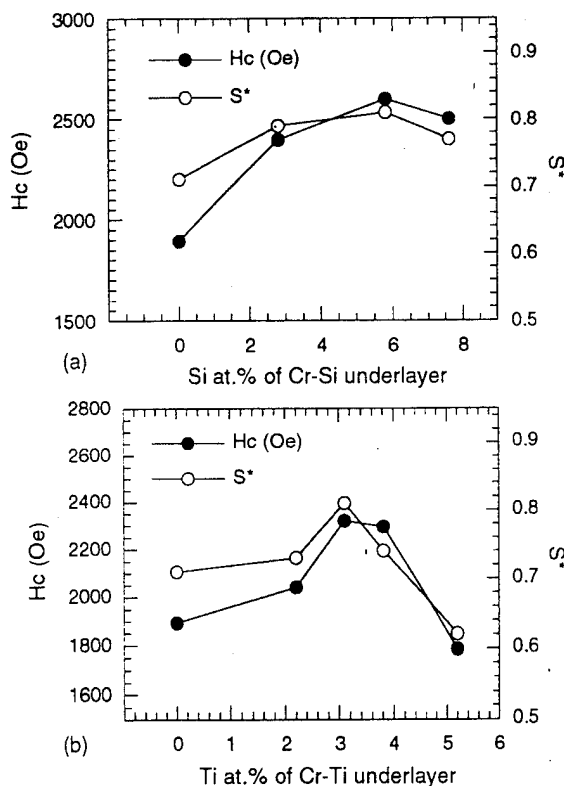

FIG. 2. Magnetic properties of CoCrPt films deposited on (a) Cr-Si and (b) Cr-Ti underlayers as a function of Si and Ti concentration.

further increase in Si content. In addition, S^* increased up to 0.80 with increasing Si content in the Cr-Si underlayer. The Cr-Si underlayer significantly improves magnetic properties (H_c , S^*) of CoCrPt films sputtered at room temperature. Figure 2(b) shows magnetic properties of CoCrPt films deposited onto a Cr-Ti underlayer as a function of Ti concentration. The effect of the Cr-Ti underlayer on H_c and S^* of CoCrPt films was similar to that of the Cr-Si underlayer. With increasing Ti content, H_c initially increased to a maximum value of 2320 Oe at 3.1 at. % Ti, and then decreased to 1800 Oe with further increase in Ti content. S^* increased to 0.81 at 3.1 at. % Ti but decreased to 0.62 at 5.1 at. % Ti. The appropriate amount of Ti addition to the Cr underlayer appears to enhance both H_c and S^* of CoCrPt films. This result is consistent with Shiroishi *et al.*'s report,⁵ although the optimum Ti concentration for improving magnetic properties is much higher in their report than in this study.

The origin of the H_c and S^* enhancement caused by Cr-Si and Cr-Ti underlayers was investigated by observing the grain morphology and crystallography using TEM and XRD. Figures 3(a) and 3(b) display the x-ray diffraction patterns of CoCrPt films sputtered on Cr-Si and Cr-Ti films at room temperature. For the Cr-Si films, independent of Si concentration, preferred orientation of Cr was almost constant, while the FWHM of the (200) peak became wider with increasing Si content, indicating a decreasing grain size. This result is further confirmed by TEM grain morphology of Cr-Si films. The Cr-Si and Cr films sputtered at room temperature showed a predominant (200) texture of simple cubic structure mixed with a minor (110) peak of body centered

FIG. 3. Change in x-ray diffraction spectra of CoCrPt films sputtered on (a) Cr-Si and (b) Cr-Ti underlayers with increasing Si and Ti concentration.

cubic (bcc) structure, contrary to a frequently reported texture of bcc (110) at room temperature or low substrate temperature,^{6,7} while the Cr films sputtered at 200 °C showed only (110) texture. This effect is possibly due to the difference in quenching rate of Cr adatoms resulting in metastable simple cubic (200) by altered surface mobility and diffusion. However, as the Ti content of Cr-Ti films increased, the (200) peak diminished and the bcc (110) peak intensity increased. Accordingly, the crystallography of the CoCrPt films altered with increasing Ti concentration in the Cr-Ti underlayer. With increasing Ti content in the Cr-Ti underlayer, the Co(10 $\bar{1}$ 0) texture appears to increase by the enhanced epitaxial growth of Co crystallites whose c axis aligns to the film plane, resulting in the increased H_c and S^* , as above shown in Fig. 2(b).

The plane-view TEM micrographs (Fig. 4) show the important effect of Si addition in Cr-Si films on grain morphology. As shown in diffraction patterns, crystallography was not affected by Si concentration of Cr-Si films. The Cr films sputtered at room temperature showed irregularly shaped grains with voided boundaries, although the films sputtered at 200 °C exhibited highly oriented, uniform grains. This difference in Cr grains with substrate heating temperature is

FIG. 4. Plane view of TEM micrographs of (a) Cr, (b) CrSi_{5.8}, and (c) CrTi_{3.1} films sputtered at room temperature.

FIG. 5. Plane view of TEM micrographs of CoCrPt films sputtered on (a) CrSi_{5.8} and (b) CrTi_{3.1} underlayers at room temperature.

considered to result in the low S^* of CoCrPt films sputtered at room temperature. However, the grain morphology of Cr-Si films became more uniform than that of Cr films and the grain size slightly reduced. It is noted that fine subgrains (≈ 50 Å) inside the large grains are clearly seen in Cr-Si films, possibly indicating segregation of Si atoms at subgrain boundaries. This result is supported by the XRD pattern showing no change in lattice parameter of Cr(200) with Si content. The grain morphology of Cr-Ti films was similar to that of Cr films but, as shown in the XRD pattern, the preferred orientation of electron diffraction pattern changed from sc (200) to bcc (110).

Figures 5(a) and 5(b) show TEM micrographs of CoCrPt films sputtered on Cr-Si and Cr-Ti underlayers. The CoCrPt films grown on a Cr-Si underlayer exhibit Co grains well separated from neighboring grains without large chains of grouped fine grains that were observed for the CoCrPt films deposited on a Cr underlayer. This effect is possibly associated with the increased S^* of CoCrPt films deposited on Cr-Si underlayers, independent of the preferred orientation of Co grains. The CoCrPt films deposited on a Cr-Ti underlayer, however, showed similar grain morphology like the films deposited on a Cr underlayer. This result is due to the different grain morphology of Cr-Si and Cr-Ti underlayer films that control the film growth of CoCrPt. Cross-sectional TEM micrographs (Fig. 6) also indicate that, for the CoCrPt films deposited on a Cr underlayer, the Co grains grow nonuniformly with irregular shapes. On the other hand, the Co grains of CoCrPt films grown on Cr-Si underlayers appear to be more uniform and better aligned along the growth direc-

FIG. 6. Cross-sectional TEM micrographs of (a) CoCrPt/Cr (200 °C), (b) CoCrPt/Cr (room temperature), (c) CoCrPt/CrSi_{5.8} (room temperature), and (d) CoCrPt/CrTi_{3.1} (room temperature).

tion than those of CoCrPt films deposited on a Cr underlayer. The fine Co grains of CoCrPt films deposited on a Cr-Ti underlayer appear to grow on a single Cr-Ti column. It is concluded that the modified grain morphology or crystallographic orientation of Cr underlayer by Si or Ti alloying plays an important role in changing the Co grain morphology as well as the preferred orientation, thereby offering the possibility of fabrication of high performance recording media at room temperature.

Ultrahigh vacuum SQUID magnetometry study of the magnetic properties of Co/Co-oxide thin films

S. Spagna^{a)} and M. B. Maple

Institute for Pure and Applied Physical Sciences, University of California, San Diego, La Jolla, California 92093

R. E. Sager

Quantum Design Inc., San Diego, California 92121

Exchange coupling between Co and Co-oxide in bilayer and trilayer thin-film structures has been studied using a recently developed ultrahigh vacuum SQUID magnetometer (UHVSQM) system. Using this novel technique, newly deposited Co films from a separate molecular beam epitaxy facility were transported into the UHVSQM without breaking vacuum and magnetically characterized before and after *in situ* room temperature oxidation. Field-cooled hysteresis measurements performed at low temperatures indicate the presence of a complex antiferromagnetic Co-oxide domain structure as a result of oxidation. The stability of the magnetic structure is determined by competition between frustration generated at the interface when the ferromagnetic Co moments are reversed and stabilizing antiferromagnetic anisotropy which becomes large only at low temperatures (<150 K). © 1996 American Institute of Physics. [S0021-8979(96)66508-9]

Exposure of thin Co films at room temperature to large quantities of oxygen, or even diluted oxygen in the form of air, results in partial oxidation of the film which passivates the surface forming a well-defined thin oxide layer approximately 20 Å thick.¹⁻³ Due to the low magnetic moments of the Co²⁺ ions within the thin Co oxide layer, the long-range antiferromagnetic (AF) order that is known to occur in the bulk Co oxide⁴ is extremely difficult to study directly in this thin passivating layer. However, information about the magnetic ordering of the Co²⁺ ions can be obtained from the exchange coupling of the Co²⁺ ions in the oxide to the metal Co atoms. In Co/Co-oxide magnetic structures, exchange coupling is manifested in a dramatic increase in coercivity and displacement of the hysteresis loop along the field axis for samples that have been cooled in an applied magnetic field to a temperature at which the anisotropy of the Co oxide is large.^{5,6} This complex of anomalies is commonly associated with the phenomenon of "exchange anisotropy."

In this paper, we demonstrate the application of a general purpose ultrahigh vacuum (UHV) compatible SQUID magnetometer (UHVSQM) system⁷ we have developed to obtain magnetic information regarding the thin AF Co-oxide layers via exchange coupling to the ferromagnetic (FM) Co film on which the Co-oxide forms. In using this system, polycrystalline Co thin-film samples, grown by electron-beam evaporation on Si(100) substrates in a molecular beam epitaxy (MBE) facility (base pressure $\sim 1 \times 10^{-10}$ Torr), are transported to the UHVSQM without breaking vacuum and characterized magnetically. The magnetic characterization consists of magnetization versus magnetic field hysteresis

measurements in fields up to one tesla, down to 20 K, and in a variable vacuum environment to pressures as low as 10^{-10} Torr. Comparison of the magnetic properties obtained from the low-temperature magnetization versus applied magnetic field hysteresis loops, before and after oxidation, yields useful information concerning exchange anisotropy and, in turn, the underlying Co-oxide magnetic structure.

Figure 1 shows the striking effect of the oxidation process after cooling in a field of 1 T and measuring magnetization versus magnetic field hysteresis loops of an 80 Å Co/Si(100) sample at 20, 50, and 150 K. A number of important features can be identified. Before oxidation, the magnetization curves are symmetric and exhibit small coercive fields, reflecting negligible anisotropy of the virgin FM Co films. After oxidation, the hysteresis loops are markedly broadened and shifted along the field axis. These observations provide evidence that the spins of the Co²⁺ ions within the oxide film act as pinning sites, impeding the free-spin rotation of neighboring FM Co atoms, thus increasing the overall coercivity of the sample. The overall coercivity is defined as $H_c = 1/2|H_c^l - H_c^r|$, where H_c^l and H_c^r are the coercive fields corresponding to the left and right of the hysteresis loops. The field offset is best described in terms of an effective internal "exchange field"^{5,6} H_E , defined as $H_E = 1/2|H_c^l + H_c^r|$, which arises from the AF interface and acts in the same direction as the previously applied magnetic field. As any amount of oxidation results in a shift of the hysteresis loop, these measurements indicate that prior to the oxidation treatment no substantial contamination occurred from the time the sample was grown until the completion of the first set of hysteresis loops (a period of approximately 5 h).

Because the interface is the source of the exchange field,

^{a)}Quantum Design Inc., San Diego, CA 92121.

FIG. 1. One tesla field-cooled hysteresis loops measured at 20, 50, and 150 K for a 80 Å Co/Si(100) sample.

a detailed understanding of the AF Co-oxide magnetic structure requires a combination of measurements which probe the morphology of the metal-oxide interface as well as its magnetic properties. A depth profiling technique, employing Auger electron spectroscopy (AES) in conjunction with 1 keV Ar⁺ ion sputter etching was utilized to characterize the morphology of the oxidized samples. The profiles were reproducible apart from minor thickness variations (± 5 Å) due to deposition nonuniformities. Figure 2 shows the normalized Auger peak height for the strongest Co(LMM), O(KLL),

FIG. 2. AES depth profile of a 23 Å Co-oxide/67 Å Co bilayer structure. The inset shows a simplified spin planar model for an atomically flat AF-FM interface.

and Si(LMM) transitions for an oxidized 80 Å Co/Si(100) sample. Qualitatively, the growth of the Co-oxide layers deduced from these measurements produces separate spatially well defined regions. The first region (shown in white in Fig. 2), results from an oxidation reaction front in which oxygen molecules dissociatively chemisorb to the oxide, trap electrons, and finally combine with the metal ions to form an oxide layer approximately 23 Å thick. This first region terminates at the metal-oxide interface, adjacent to the Co metal layers shown in gray in Fig. 2. If this interface were atomically flat, cooling of the bilayer in a large applied magnetic field would result in alignment of the Co spins (\uparrow) in the metal film, forming a single magnetic domain. By the same interaction, the spins (\uparrow) of the AF oxide next to this interface would also align ferromagnetically, creating an "uncompensated" spin configuration (where an interfacial energy difference $\Delta\sigma$ per unit area favoring a specific FM orientation is created in the cooling process) as schematically shown in the inset of Fig. 2. Below the Néel temperature of the oxide, the next spin plane (\downarrow) in the AF Co-oxide layers nucleate so as to be oppositely directed to the first plane. Once the oxide spins are arranged in this configuration, and the anisotropy of the AF is strong, the FM spins tend to be locked in the field cooling direction thus resulting in a shift along the field axis. Although this model, involving a simplified AF magnetic structure comprised of alternating ferromagnetically coupled planes, qualitatively reproduces the features of exchange coupling, the Auger depth profile indicates a relatively broad and atomically rough metal-oxide interfacial region. There is increasing evidence⁸⁻¹⁰ that roughness and chemical inhomogeneity on an atomic scale between the metal and oxide layers results in nonuniform exchange interactions creating a complex AF magnetic structure. Within this framework, when the FM forms a single domain during magnetic field cooling, the random exchange field transferred across the interface causes the AF to break up into lateral domains to minimize the random interfacial field energy. However, evidence for a domain structure from hysteresis loop measurements of Co/Co-oxide bilayers is difficult to obtain because of the small thickness of the oxide layers formed at room temperature. Comparison of the magnetic properties, before and after oxidation (Fig. 3, upper panel), indicates that exchange coupling effects after oxidation develop gradually and become large only at low temperatures. The loss of exchange field above 150 K can be attributed to the metastability of the thin AF magnetic structure which is strongly affected by destabilizing forces that are generated upon rotation of the Co spins within the metal film. This result is consistent with previous work on oxide passivated Co fine particles,^{12,13} where it was concluded that the underlying cause of the AF "magnetically soft" domain state may be attributed to a crossover to superparamagnetic behavior due to the extremely thin nature of the oxide layers. The gradual recovery of the saturation moment of the Co²⁺ ions in the oxide layers at high temperature (Fig. 3, lower panel) supports this prediction indicating that the frustration generated at the interface during hysteresis measurements is sufficiently high to suppress AF long-range ordering and induce a crossover to superparamagnetic behavior.

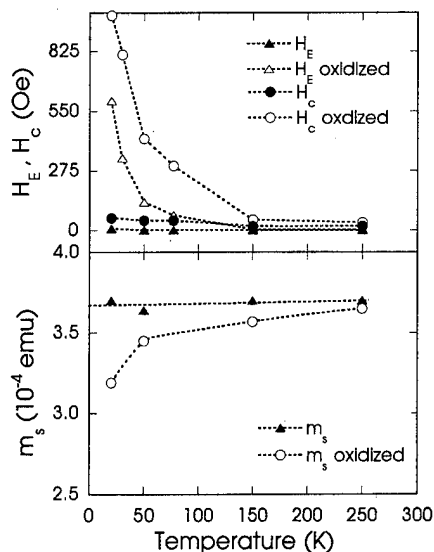

FIG. 3. Temperature dependence of coercive force H_c , exchange field H_E , and saturation moment m_s (lower panel) before (\blacktriangle), and after (\circ), complete oxidation of a 80 Å Co/Si(100) thin-film sample.

Figure 4 compares 1 T field-cooled hysteresis loops measured at 50 K, before and after a 150 Å Co deposition on a 25 Å Co-oxide/100 Å Co bilayer. The dramatic enhancement of the coercive and exchange fields that results suggests an increased effectiveness of the oxide layer. Furthermore, in contrast to the bilayer, the shape of the hysteresis loop for the trilayer structure is considerably different, reminiscent of two superimposed unequal loops shifted toward opposite sides of the field axis. These findings seem to suggest that the spin distribution in the oxide is nonuniform on a macroscopic scale but more effectively "frozen" during the hysteresis measurements. Figure 5 shows the Auger depth profile for the trilayer structure which reveals two metal-oxide interfaces which separate an oxide layer (~ 50 Å thick), sandwiched between two Co metal layers 100 Å in thickness. Apparently, the additional deposition results in a partial oxi-

FIG. 4. Comparison of hysteresis loops of (a) 25 Å Co-oxide/100 Å Co bilayer, and (b) 100 Å Co/50 Å Co-oxide/100 Å Co trilayer structures.

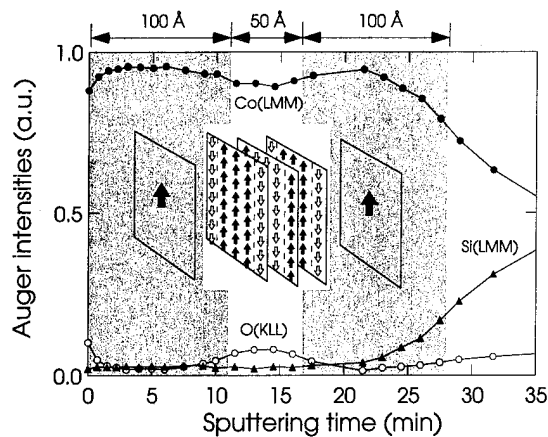

FIG. 5. AES depth profile for 100 Å Co/50 Å Co-oxide/100 Å Co trilayer structure. The inset shows a simplified AF domain planar structure arising from a random field at the metal-oxide interfaces.

dation of the Co atoms impinging on the oxide surface, producing a thicker and magnetically more stable oxide film. The inset of Fig. 5 depicts a simplified planar model for the AF structure deduced from these measurements. Assuming a random field at the interface, when the FM forms a single domain [shown by a global (\uparrow) FM moment] in an external field, it is energetically favorable for the AF to break up into domains (\uparrow, \downarrow) to minimize the net interfacial anisotropy energy. The presence of a domain state, coupled with a coercivity mechanism within the AF which anchors the domain state in place, leads to the exchange anisotropy effects. The resultant hysteresis loop is then the sum of oppositely magnetized AF domains which produce two shifted loops in opposite directions along the magnetic field axis. Evidence of a domain pattern has also been obtained using the magneto-optic Kerr effect in thick Co/CoO bilayers.¹¹

Institut f. Experimentalphysik III, Ruhr-Universität, 44780 Bochum, Germany

Q. Wang and H. Zabel

Institut f. Experimentalphysik IV, Ruhr-Universität, 44780 Bochum, Germany

Co/Mn multilayers were prepared by rf sputtering onto single-crystal MgO(001) and Al₂O₃(11 $\bar{2}$ 0) substrates resulting in, respectively, (001)- and (111)-oriented layers. The structure was thoroughly analyzed by x-ray scattering in various geometries. For the magnetic investigations, ferromagnetic resonance (FMR) was applied. Complementary measurements employed the magneto-optical Kerr effect and Faraday balance magnetometry. Results for the in-plane anisotropy, the surface anisotropy, the magnetization, and the FMR linewidth are presented. The comparison with other Co-based multilayer system indicates that both the structural and the magnetic properties of the Co/Mn system are more complicated than in the case of systems with a presumably weaker electronic interaction at the interface. © 1996 American Institute of Physics. I. INTRODUCTION

Thin and ultrathin magnetic layers offer fascinating possibilities for studying structure and magnetism in low dimensions and for manipulating material properties in a way which is not accessible in the bulk. Many epitaxial systems have been studied within the last years. Some of these turned out to be suitable as model systems (e.g., Co/Cu in different orientations) while others exhibit a more sophisticated and specific behavior such as, e.g., Co/Cr(001).¹ In the more complicated systems one may find changes of the structural phase accompanied by a change of the magnetic properties of the ferromagnetic material or an impact on the magnetism of, e.g., Co caused by the nontrivial spin structure of its epitaxial partner.

Due to its unusual bulk properties, Mn can be suspected to be an extremely interesting but also difficult candidate for thin-film investigations. Several remarkable aspects have been pointed out in the pioneering work of Ounadjela and co-workers on Co/Mn superlattices grown by evaporation on Ru(0001).² Mn is the only transition metal which has no simple bulk phase (fcc, bcc, or hcp) at room temperature. Four different structures are found as a function of temperature with a wide range of atomic volumes and also magnetic order is possible.

In this contribution, we present ferromagnetic resonance (FMR) measurements on rf-sputtered Co/Mn multilayers on MgO and sapphire substrates. We concentrate on the (001)-oriented samples in this report on our first results. The data are compared to those obtained for the (111) orientation on sapphire.

II. SAMPLE PREPARATION AND EXPERIMENTAL

The Co/Mn multilayers were prepared by rf sputtering on MgO(001) and Al₂O₃(11 $\bar{2}$ 0) substrates with Co as the first layer. The thicknesses of the Co layers, t_{Co} , cover a range from 10 to 50 Å and the thickness of the Mn layers ranges

from 5 to 35 Å. The samples consist of ten superlattice periods. For both Co and Mn, the sputtering rates were 0.1 Å/s at a substrate temperature of 100 °C. The structural properties of the layers were thoroughly characterized by x-ray diffraction in various configurations.³ As in the rest of the paper, we concentrate on the (001)-oriented samples. Both Co and Mn were found to exhibit the (metastable) strained fcc (fct) structure. The total roughness was relatively high (about 5–8 Å). By diffuse scattering it was found that the larger fraction of the roughness was correlated so that one may still speak of a well-defined superlattice structure. More details about our x-ray investigations can be found in Ref. 3.

All samples were measured at room temperature by FMR as a function of the external field orientation (with the in-plane angle ϕ and the out-of-angle θ) in a 9 GHz cavity. Complementary measurements were performed at 17 and 69 GHz in a shortened waveguide setup. The maximum magnetic field available was 31 kG. In most of the measurements the limiting factor for the accuracy of the determination of the magnetic parameters was the linewidth of the resonance curves (see below; for remarks on the absolute accuracy of the apparatus and measurements on samples exhibiting broad lines see, e.g., Ref. 4). Additionally, the magnetic investigations included magneto-optical Kerr-effect (MOKE) measurements and Faraday balance magnetometry.³

III. RESULTS AND DISCUSSION

The results of the angular dependent FMR measurements are analyzed using the energy density formalism for the resonance condition.⁵ For the (001)-oriented films, the external field energy ($-\mathbf{M} \cdot \mathbf{H}$), the cubic magnetocrystalline anisotropy $\{-(K_1/2)\cos^4\Theta - (K_1/8)\sin^4\Theta[3 + \cos(4\phi)]\}$, and the effective out-of-plane anisotropy energy as a sum of demagnetizing energy and surface anisotropy K_s are the relevant contributions.⁶ For the resulting resonance relations,

^{a)}Also with Academy of Sciences, Institute of Physics, 18040 Prague 8, Czech Republic.

FIG. 1. Effective out-of-plane anisotropy versus $1/t_{\text{Co}}$ for the series on MgO(001).

the reader is referred to the above references. As done by many authors, the effective magnetization is defined as

$$4\pi M_{\text{eff}} = 4\pi M - 2 \frac{K_s}{M t_{\text{Co}}}. \quad (1)$$

In Fig. 1, we plot $4\pi M_{\text{eff}}$ as a function of the inverse thickness. The slope of the straight line is $110 \text{ kG } \text{\AA}$ which corresponds to $K_s = 0.4 \pm 0.1 \text{ erg/cm}^2$ assuming the bulk value for M (1430 emu/cm^3). However, in our magnetization measurements with a Faraday balance we found the magnetization to be thickness dependent (see below), so that the real K_s value is reduced.

The thickness dependence of the out-of-plane resonance field for the (111)-oriented samples (not shown) yielded a surface anisotropy of $K_s = 0.35 \pm 0.15 \text{ erg/cm}^2$ (again assuming $M = 1430 \text{ emu/cm}^3$). The K_s values are in the range of that reported by Ounadjela *et al.* for the layers prepared by evaporation ($K_s = 0.5 \text{ erg/cm}^2$).² If one tries to compare these results to Co/Cu which was also investigated in the (001) and in the (111) orientation it is worth remarking that for Co/Mn, K_s has the same (positive) sign for both orientations while for Co/Cu the sign is different, i.e., K_s favors out-of-plane magnetization for Co/Cu(111) and in-plane magnetization for Co/Cu(001).⁷

For the *in-plane* anisotropy, it is often much more difficult to extract a clear thickness dependence. In the series of the (001)-oriented layers, the magnetocrystalline anisotropy field parameter $2K_1/M$ was found in the range of about 0.6 – 0.8 kG , apparently without systematic t_{Co} dependence for the thicker layers. A sample with $t_{\text{Co}} = 45 \text{ \AA}$ is shown in Fig. 2. In contrast, for t_{Co} below 15 \AA , the anisotropy was less than half of this value.

We think that this behavior is connected rather with the growth and the structural characteristics than with intrinsic surface effects. At low thicknesses, the structure may not be fully developed and interdiffusion effects which are not negligible in the present samples may play an important role. This may also be consistent with the magnitude of $2K_1/M$ for thicker samples which is still slightly reduced in comparison with, e.g., those obtained on Co/Cu(001).⁷

FIG. 2. In-plane angular dependence of the resonance field for $[\text{Co}_{45}\text{Mn}_{15}]_{10}$ grown on MgO(001).

In Fig. 3, we show an example of the (111)-oriented layers. The 60° (sixfold) symmetry is obvious with a difference of the resonance field between hard and easy axis of the order of 25 G . This corresponds to values of about 0.3 G for the parameter K_4/M if described in terms of the hexagonal anisotropy energy $[K_4 \sin^6 \Theta \cos(6\phi)]$.⁸ In comparison to our investigations of molecular beam epitaxy (MBE) grown Co/Cu(111) superlattices on the same substrates (sapphire),⁹ the anisotropy is weaker in the present samples. However, the fact that it is clearly resolved can still be taken as an indication of a good structural in-plane coherence.⁹

In addition to the magnetocrystalline anisotropy, several samples also exhibited a uniaxial in-plane contribution $[K_u \sin^2 \Theta \cos^2(\phi - \phi_u)]$ which is quite often found in thin films. As the magnitude of the corresponding effective field $2K_u/M$ was small (of the order of 10 G) and no simple systematic behavior was found we do not focus on this point.

As already indicated above, the resonance lines were relatively broad in some cases. For the (001)-oriented samples, the linewidth values were found between about 150 and 460 G for the in-plane easy axis and between 250 and 470 G for the hard axis at X-band frequencies with the general tendency of broader lines for lower thicknesses. The

FIG. 3. In-plane angular dependence of the resonance field for $[\text{Co}_{45}\text{Mn}_{15}]_{10}$ grown on sapphire.

linewidths are higher at higher frequencies due to the intrinsic (Gilbert) damping but there are significant nonintrinsic broadening contributions (see also Refs. 6, 7, and 10). The linewidths of the (111) layers were lower, without significant angular dependence. As it was found in Ref. 2 for MBE-grown Co/Mn on Ru(0001), the lines in perpendicular orientation were usually broader.

Besides the roughness of the interface and other structural imperfections [maybe particularly important in the strongly anisotropic (001)-oriented layers] also a significant strain³ may contribute to the line broadening in the present superlattices.

Unfortunately, because of the linewidth limiting the accuracy for all extracted parameters, it was not possible yet to determine the g -factor g with a precision sufficient to decide whether g deviates from the bulk value or not. This can be tried in future experiments using additional frequencies up to 92 GHz, and it should be particularly interesting as in systems with the partner of the ferromagnetic metal having an only partially filled $3d$ band, the electronic interaction at the interface may be expected to give rise to changes in the bandstructure which influence g (see also Ref. 4).

Our Faraday balance measurements which are reported in more detail in Ref. 3 yielded a reduction of the magnetization with respect to the bulk value corresponding to the moment of about two or three monolayers of Co. No evidence was found for a ferromagnetic contribution of Mn.

In conclusion, we have presented ferromagnetic resonance measurements on sputtered Co/Mn in the (001) and (111) orientation. The surface anisotropy K_s was determined. If compared to the Co on Cu which can also be prepared in both orientations with Co in the fcc phase, the results for the thickness dependence of the in-plane anisotropy and also the linewidth and the reduced magnetization may indicate that Co on Mn is a much more complicated system as it was pointed out also in Ref. 2. More data seem to be required for

this epitaxial system. It should also be kept in mind that CoMn alloys exhibit invar properties which may play a role under certain conditions, e.g., very thin layers and high interdiffusion. This will be addressed in future investigations.

Structural and magnetocrystalline anisotropy contributions to the blocking temperatures of $\text{Ni}_x\text{Co}_{(1-x)}\text{O}$ exchange couples (abstract)

Kentaro Takano and Ami E. Berkowitz

Department of Physics and Center for Magnetic Recording Research, CMRR-0401, University of California, San Diego, La Jolla, California 92093-0401

Wei Cao and Gareth Thomas

Department of Material Science and Mineral Engineering, University of California, Berkeley, California 94720

The simple spin and crystal structure of the antiferromagnetic (AF) monoxide $\text{Ni}_x\text{Co}_{1-x}\text{O}$ facilitates structural characterization and modeling of its magnetic properties. $\text{Ni}_x\text{Co}_{1-x}\text{O}$ is also receiving technological attention for biasing magnetoresistive sensors as a robust alternative to FeMn. In this work, we studied the thickness dependence of the AF layer on the exchange field created through interfacial exchange coupling between $\text{Ni}_x\text{Co}_{1-x}\text{O}$ and $\text{Ni}_{81}\text{Fe}_{19}$ films. The $\text{Ni}_x\text{Co}_{(1-x)}\text{O}$ films were reactively sputtered on silicon substrates and capped with a 300 Å $\text{Ni}_{81}\text{Fe}_{19}$ layer. An additional silver layer was deposited as an oxidation barrier. An exchange field was observed on all the exchange couples with the $\text{Ni}_x\text{Co}_{(1-x)}\text{O}$ thickness ranging from 25 to 1000 Å. The exchange couples were characterized using transmission electron microscopy (TEM) to yield information on the orientation, structure, and size of the crystallites. The films were polycrystalline with columnar grains. For oxide thicknesses below 300 Å, the film was randomly oriented but developed a texture with a preferred orientation for thicker films. We found that the blocking temperature, at which the exchange field goes to zero, decreases with decreasing oxide thickness. The blocking temperature is relatively thickness independent for higher thicknesses but decreases rapidly below a certain thickness. The decrease in the blocking temperature does not appear to be consistent with a finite size scaling law.¹ Instead we modeled this behavior to take into account the temperature dependence associated with the changing microstructure of the AF layer with thickness, in particular the size of the crystallites. In thick oxide films, the blocking temperature corresponds to the AF ordering temperature, the Néel temperature. The decrease of the blocking temperature below the Néel temperature suggests at the competing magnetic and thermal energies necessary for exhibiting unidirectional anisotropy. The thickness sensitivity of the blocking temperatures of the AF monoxides are found to be strongly dependent on their magnetocrystalline anisotropy. © 1996 American Institute of Physics. Rotatable anisotropy in radio frequency diode sputtered iron thin films

W. Win, E. J. Yun, and R. M. Walser

I/UCR Center for Magnetism, The University of Texas at Austin, Austin, Texas 78712

Iron films deposited by rf diode sputtering exhibited a robust, rotatable hysteresis loops with nearly perfect squareness; i.e., $\sim 100\%$ of M_s rotates to any in-plane direction x , following the application of $H_x > H_c$, and exhibits a stable uniaxial hysteresis for further variations in H_x . The rotatable anisotropy (RA) observed is highly reproducible on various substrates (glass, silicon, and alumina), and is unaffected by variations in; substrate temperature (to 300 °C), deposition rate (15–300 Å/min), in-plane orienting magnetic fields (to 200 Oe), and annealing at temperatures to 370 °C in a large magnetic field (to 1.3 kOe). RA was absent only in films deposited in higher Ar pressures.

I. INTRODUCTION

Rotatable anisotropy (RA) has been observed in iron films prepared by rf diode sputtering. In these films, a rectangular easy axis hysteresis loops with abrupt transitions and high remanence can be observed in an arbitrary in-plane direction by applying a field that exceeds the typical coercivity of ~ 10 –12 Oe. The rotatable anisotropy of these films is extremely robust and highly reproducible.

There are no previous reports of RA in Fe thin films deposited by rf diode sputtering. RA has been observed in evaporated, negative magnetostrictive Fe thin films that exhibit stripe domains.^{1–3} However, the RA associated with stripe domains is markedly different from that observed in rf diode sputtered films. In addition, Fe films obtained by rf diode sputtering are markedly different from those recently obtained by rf magnetron,^{4,5} dc diode,⁵ and dual ion beam⁶ sputtering. The purpose of this article is to discuss the results of experiments to characterize RA in rf diode sputtered Fe films. Experiments aimed at determining the origin of the observed RA will be presented elsewhere.

II. EXPERIMENT

The iron films described in this article were deposited by rf diode sputtering from a 5 in. iron target with a purity of 99.95%. The base pressure of the system was below 2.5×10^{-7} Torr and the Ar pressure during sputtering was between 5 and 30 mTorr. Films were deposited in both the static and rotational deposition modes. In the rotational deposition mode, the substrates were rotated under the Fe target at

6 rpm. Substrate bias in the range from -40 to -50 V was occasionally applied during deposition. The static and rotational deposition rates were ~ 270 –300 Å/min, and ~ 15 –18 Å/min, respectively. Films with 1000 Å thickness were deposited on cover glass slides, silicon wafers, and alumina substrates. The Fe films were deposited either at ambient, or at 300 °C substrate temperatures. In-plane bias magnetic fields of 200 Oe were applied during the deposition of some films. The effect of temperature on RA was investigated by annealing a film to 370 °C in a vacuum of 4.5×10^{-6} Torr. The effect of applying a large (1.3 kOe) in-plane field parallel to a predetermined axis during annealing was also investigated.

The B – H loops of the films were obtained, at room temperature, using either a low field hysteresis loop tracer (drive field ≤ 100 Oe) or a vibrating sample magnetometer (VSM). The room temperature resistivity was measured with a four-point probe method.

III. RESULTS AND DISCUSSION

The rotatable anisotropy in the rf diode sputtered iron films was characterized by measuring their in-plane hysteresis loops as a function of the orientation and amplitude of in-plane driving fields. A typical hysteresis loop of a ~ 1000 Å thick Fe film deposited on glass is shown in Fig. 1. When a field $H_x > 10$ Oe was applied in an arbitrary in-plane direction x , the magnetization of this film rotated to that direction,

FIG. 1. Hysteresis loop of Fe film deposited on glass substrate (10 mTorr Ar). The magnetic field was applied along an arbitrary direction.

FIG. 2. Variations in film magnetization with the angle ϕ (see text) that a saturated Fe film is rotated in fields; $H=0$, $H < H_c$, and $H > H_c$.

FIG. 3. Magnetization observed during (\square), and following (\bullet), the application of H_{\perp} perpendicular to a direction of prior saturation.

where it exhibited a stable square hysteresis loop for further variations in H_x . Independent of the orientation of the film, the squareness ratio M_r/M_s was typically between 0.95 and 0.98.

Figure 2 illustrates the RA in a 1000 Å iron film with $H_c \approx 12$ Oe. The sample magnetization was first saturated along an arbitrarily selected axis x . A stationary dc field was then applied along this axis, and the sample rotated so that the axis of initial saturation made an angle ϕ with the direction of the applied field. Figure 2 plots the variations in the film magnetization along the axis of initial saturation with ϕ , for applied fields of $H_x = 0$, $H_x = 8.8$ Oe $< H_c$, and $H_x = 18.2$ Oe $> H_c$. For $0 < H_x < H_c$, the magnetization exhibited a uniaxial anisotropy. The rotatable anisotropy was evidenced by the near independence of the magnetization on the rotation angle, when a field $H_x > H_c$ was applied.

The rotation of the easy axis was confirmed by measuring the magnetization perpendicular to a previously saturated direction as a function of the applied field. In this experiment, a dc field large enough to saturate the sample, was applied in the VSM along an arbitrary direction in the film plane. The sample was then rotated 90° around the film normal to a new direction. The in-plane magnetization in the new direction was initially zero as expected. The magnetization was measured (Fig. 3) with the field applied along the 90° direction (H_{\perp}); first while it was increased from zero to above H_c , and then (as shown by the arrows) while it was increased to zero. Figure 3 plots the magnetization measured

FIG. 4. Hysteresis loops of Fe films deposited on silicon (solid) and alumina (dashed) substrates. (The hysteresis loop of an Fe film deposited on a glass substrate is shown in Fig. 1.)

TABLE I. Substrate dependence of the magnetic properties of Fe films with thickness ≈ 1000 Å.

Substrate	M_s (G)	H_c (Oe)	ρ ($\mu\Omega$ cm)
Glass	21 204	9	14.9
Si	20 711	8	15.5
Alumina	20 840	12	14.8

while H_{\perp} was present (open squares), and the remanent magnetization after H_{\perp} was removed (solid circles). The remanence of these minor hysteresis loops were observed to be typically $>95\%$. When H_{\perp} exceeded H_c , the $M = M_s$ and the $M_r \approx M_s$, indicating that the magnetization and uniaxial hysteresis had completely rotated to the new direction.

For dc and ac magnetic fields larger than H_c , the in-plane magnetization rotated to the field direction independent of the initial film orientation. However, for $H_{ac} < H_c$, the rotatable hysteresis loop collapsed into a horizontal line with zero slope, and remained at zero when the sample was rotated. Hence, the hard-axis minor loop was not observable with H_{ac} . A finite slope along the hard axis was observed for dc magnetic fields in the range $0 < H_{dc} < H_c$. $M(0) = 0.98 M(H_{dc})$ was observed throughout this H_{dc} range. When $H_{dc} \geq H_c$, the magnetization remained aligned with the direction of H_{dc} , when the sample was rotated.

The robustness of the RA was investigated by: (a) varying the substrate material, (b) applying a magnetic bias field during deposition, (c) heating the substrate, and (d) annealing the as-deposited films. Fe films were deposited by rf diode sputtering onto cover glass slides, silicon wafers, and alumina substrates. RA was observed in the films deposited on all of these substrates. Furthermore, the coercivity, squareness ratio, and resistivity were nearly independent of the substrate. The hysteresis loops of Fe films deposited on silicon and alumina substrates are shown in Fig. 4 to illustrate the similarity in their hysteresis loops. The typical magnetic properties of films deposited on these substrates are summarized in Table I.

Rotatable anisotropy was observed in Fe films with, or without, a 200 Oe bias magnetic field applied in-plane during the deposition. The properties are summarized in Table II.

After annealing at 370 °C in vacuum in the presence of a strong in-plane field (1.3 kOe), a slight increase in M_s (from 21 181 to 21 432 G) was accompanied by small decreases in H_c (from 12 to 10 Oe) and resistivity (from 16 to 13.6 $\mu\Omega$ cm). However, the rotatable anisotropy was completely unaffected by this annealing process. The RA was also unchanged in films deposited on substrates held at elevated temperatures to 300 °C.

TABLE II. Magnetic properties of ≈ 1000 Å thick Fe films deposited with and without H_{ext} field.

H_{ext} (Oe)	M_s (G)	H_c (Oe)	ρ ($\mu\Omega$ cm)
0	21 181	12	16.03
200	21 486	12	14.4

FIG. 5. Isotropic hysteresis loop of rf diode sputtered 1000 Å Fe film deposited with Ar pressure=30 mTorr. (See Fig. 1 for hysteresis loop of Fe film deposited with Ar pressure=10 mTorr.)

RA could be eliminated in the rf diode sputtered Fe films only by increasing the Ar pressure (to 30 mTorr). As shown in Fig. 5, the resulting films were isotropic with $H_c \approx 300$ Oe. The dependences of the magnetic properties and electrical resistivity of the Fe films on Ar pressure are shown in Figs. 6(a) and 6(b). The increase in Ar pressure was believed to increase the film porosity, reduce M_s , and increase H_c and the resistivity. The RA vanished in these films and the in-plane hysteresis loops were isotropic.

IV. SUMMARY

Fe films deposited by rf diode sputtering exhibit a previously unobserved, and exceptionally robust, rotatable anisotropy. The rf diode sputtered films were very high quality with resistivity and M_s values that were within $\pm 1\%$ of pure bulk iron. The hysteresis loops of these films were very square with $\sim 100\%$ remanence and sharp magnetization reversal transitions. The rotatable anisotropy was reproducible and unaffected by the substrate material, the application of an in-plane bias field during deposition, substrate heating, and postdeposition annealing. RA was not detected in rf diode sputtered Fe films only when they were sputtered at Ar pressures high enough to eliminate the uniaxial anisotropy. Similar RA was observed in films deposited in static and rotating deposition modes with a tenfold variation in deposition rate. The insensitivity of RA to variations in deposition

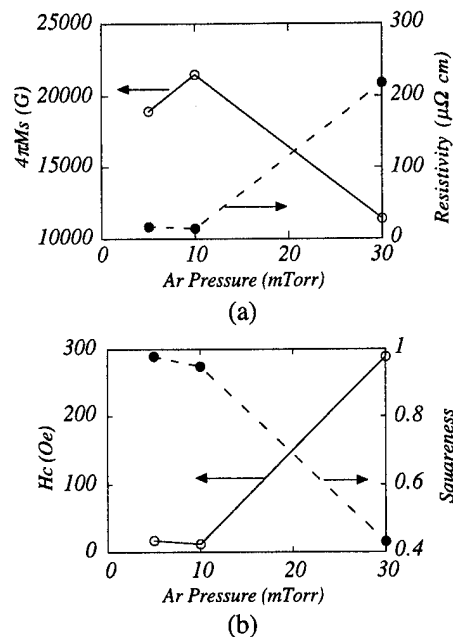

FIG. 6. Variations in: (a) $4\pi M_s$ and resistivity and (b) H_c and squareness, with Ar sputter gas pressure.

parameters suggests that the random interfacial morphology produced by rf diode sputter deposition is the important structural feature responsible for RA in Fe thin films. Investigations to confirm this are in progress.

Coupling effects in Fe/CoNbZr and Fe/Ag/CoNbZr sandwiches studied by magneto-optical techniques

M. C. Contreras, J. F.-Calleja, M. O. Gutiérrez, and M. Rivas

Laboratoire de Magnétisme et d'Optique de Versailles, C.N.R.S., 92195 Meudon Cedex, France

Experimental characterization of magnetic anisotropy, coercive field, and anisotropy dispersion of sputtered Fe/CoNbZr and Fe/Ag/CoNbZr sandwiches were carried out by transverse biased initial susceptibility (TBIS) measurements with a magneto-optic Kerr effect at both film/air and glass/film interfaces. Three different behaviors have been observed depending on the range of magnetization fluctuation. The results indicate that Fe grains play a fundamental role in the type of the dispersion (long range or short range). The results obtained from the coercive field and from x-ray diffractograms agree with those obtained by TBIS. © 1996 American Institute of Physics. [S0021-8979(96)66808-8]

INTRODUCTION

The study of ferromagnetic double-layered and sandwiched films is the basis for understanding multilayered systems. The magnetic and magneto-optical properties of the ferromagnetic sandwiched films are strongly influenced by the coupling at the interfaces. However the origin of this coupling mechanism is as yet unclear. Several investigators have suggested that a positive coupling is caused by an exchange interaction through pinholes¹ in the intermediate layer. Others²⁻⁴ have proposed the interaction between domain walls or by the ripple stray fields of ferromagnetic layers.

In this article we investigate Fe/CoNbZr and Fe/Ag/CoNbZr sandwiches by performing transverse biased initial susceptibility (TBIS) measurements and several magneto-static techniques. As is well known, TBIS measurements have their foundation in the application of a small alternating field h_{ac} and an orthogonal steady field H_{dc} , both in the film plane. Then, the susceptibility in a direction parallel to h_{ac} is measured as a function of H_{dc} . In the following, the transverse susceptibility will be called $\chi_t(\beta)$, with β the angle between the easy axis of induced anisotropy and the direction of H_{dc} .

EXPERIMENTAL PROCEDURE

The layers were prepared by sequential rf sputtering using a system which was first pumped to a pressure of 4×10^{-7} Torr. The targets were pure Fe, Ag, and an alloy of Co-Nb-Zr (CNZ). The deposition parameters were a rf power of 80 W and an Ar pressure of 6 mTorr. A water cooled glass substrate was used.^{5,6} All the sandwiches have a Fe layer in contact with the substrate.

The saturation magnetization M_s was measured with a vibrating sample magnetometer. M_s in the sandwiches ranging from 1000 to 1100 emu cm⁻³ and the in-plane M - H loops were measured by magneto-optical Kerr effect (MOKE) and a hysteresis graph.

Morphological and crystallographic structure of the films were examined by standard x-ray diffraction (XRD) of Cu $K\alpha$ radiation. All the films except the CoNbZr layer showed a polycrystalline structure. The amorphous structure of the

CoNbZr layer was confirmed by XRD, as no evidence of the crystalline order on a scale of more than a few Å was detected.

We have studied the magnetic behavior of these sandwiches by using the MOKE system to perform TBIS measurements at both film/air (f/a) and glass/film (g/f) interfaces in two different configurations: with the dc field applied along the easy axis and along the hard axis. Note that the optical penetration depth in our case is approximately 400 Å, which allows us to probe the top and the under layer of the bilayers and sandwiches in those cases in which their thickness is smaller than 400 Å. It is noteworthy that TBIS measurement is more sensitive than the measurement of the hysteresis loop: It allows us to determine very precisely the easy axis and the anisotropy field (H_k) and moreover to quantify the anisotropy dispersion distinguishing between short- and long-range magnetization fluctuations in the plane of the film whose origin is different.

H_k is obtained from the linear extrapolations to the value $\chi_{t,\beta}^{-1}=0$ in the $\chi_{t,\beta}^{-1}$ vs H curves from the high field range, β being the angle between the dc applied field and the easy axis of the film.

In real films these extrapolations for $\beta=0$ and $\beta=\pi/2$ cut the abscissa at asymmetrical points separated by $2 H_k$. We denote this asymmetry by ΔH_k . The normalized value $\Delta H_k/H_k$ is phenomenologically related with the magnetization dispersion.

The H_c/H_k ratio provides information about the prevalent mechanism in the magnetization reversal process. If this ratio is small compared to unity the dominating magnetization reversal process is characterized by nucleation of a small number of opposite domains followed by subsequent wall propagation. On the other hand, if $H_c/H_k \geq 1$ the reversal mechanism becomes more complicated, involving incoherent rotation and the nucleation of a large number of small opposite domains, spread over the whole film area.

RESULTS AND DISCUSSION

Three different behaviors are observed.

Figure 1 shows $\chi_{t,\beta}^{-1}$ vs H curves obtained for the as-prepared Fe film. Both curves present a minimum and cut the

FIG. 1. Experimental curves of $\chi(\beta)^{-1}$ vs H and linear extrapolations for the Fe layer. Squares represent $\beta=0$ and circles $\beta=\pi/2$.

abscissa at negative values, which indicate that this film is quasi-isotropic, as expected. For this film we obtain $\Delta H_k/H_k=1.6$. From x-ray diffractograms it was concluded that the Fe layer has a bcc structure with a (110) and (200) texture [the (211) reflection was absent].

In the case of CoNbZr, layer inverse susceptibility follows the law

$$\chi^{-1} = \frac{H_k}{M_s} [(h \pm 1) + b(h \pm 1)^{-1/4}], \quad (1)$$

where $h = H_{dc}/H_k$.

This can clearly be seen in Fig. 2, which shows that $\chi^{-1}(h \pm 1)^{1/4}$ vs $(h \pm 1)^{5/4}$ follows a linear law. The parameter b is known as the ripple parameter^{7,8} and represents local short-range fluctuations of magnetization. In this case $b=0.21$. Different values of H_k obtained at both interfaces can be explained by an oxidation of Zr in the film/air interface.

For the rest of the layered samples the inverse of the transverse susceptibility follows the law

$$\chi^{-1} = \frac{H_k}{M_s} [(h \pm 1) + c(h \pm 1)^{-1}]. \quad (2)$$

FIG. 2. Experimental curves of $\chi(\beta)^{-1}(h \pm 1)^{1/4}$ vs $(h \pm 1)^{5/4}$ and linear extrapolations for the CoNbZr layer. Squares represent $\beta=\pi/2$ and circles $\beta=0$.

FIG. 3. Experimental curves of $\chi(\beta)^{-1}(h \pm 1)$ vs $(h \pm 1)^2$ and linear extrapolations for sample 5. Squares represent $\beta=\pi/2$ and circles $\beta=0$.

This has been checked by plotting $\chi^{-1}(h \pm 1)$ vs $(h \pm 1)^2$ as shown in Fig. 3. Parameter c represents skew or long-range fluctuation of magnetization in the plane of the sample, that is to say, this effect implies a much higher dispersion of anisotropy than ripple effect.⁹ Due to the locally different easy direction in a particular grain, the magnetization, lying in the plane of the film, rotates with respect to the magnetization in the surroundings.

Table I reports values of b and c for the samples with the first two behaviors previously mentioned.

Table II reports values of H_k , H_c , and $\Delta H_k/H_k$ for all the samples under study. In those cases in which the thickness is larger than the penetration depth we give the values for both f/a and g/f interfaces. From XRD profiles of Fe/CoNbZr sandwiches only one peak was observed corresponding to Fe(110) texture. The peak becomes sharper when the thickness of Fe is larger, which suggests a larger grain size in samples 3 and 6, probably due to diffusion of Fe at the interfaces. The existence of the interdiffusion layer was shown by conversion Mössbauer spectroscopy.⁶ This leads to a very small value of H_k and a high $\Delta H_k/H_k$ at both interfaces that justifies the hypothesis. In the other cases this behavior has been observed mainly at the g/f interface corresponding to a Fe deposit.

The coercive fields of individual Fe and CoNbZr are 17 and 0.5 Oe, respectively, and the H_c/H_k ratio is in the first case much higher than unity and in the second case much

TABLE II. Magnetic properties of the films. When two values are given they are in the order (f/a)/(g/f).

Sample	No.	<i>t</i> (nm)	<i>H_k</i> (Oe)	$\Delta H_k/H_k$	<i>H_c</i> (Oe)
Fe	1	50	5.1	1.6	17.0
CoNbZr	2	160	14.6/11.8	0.21/0.17	0.5
Fe/CNZ	3	80/80	7.2/5.5	0.14/0.27	5.1
Fe/CNZ	4	30/30	12.4/11.6	0.10/0.13	6.0
Fe/CNZ	5	20/20	11.9	0.21	5.8
2×(Fe/CNZ)	6	2×(20/20)	8.7/8.3	0.18/0.28	4.5
Fe/Ag/CNZ	7	20/6/20	14.4/12.3	0.21/0.28	10.3
Fe/Ag/CNZ	8	20/3/20	12.4/11.0	0.23/0.17	11.6
Fe/Ag/CNZ	9	20/1.5/20	12.2/12.0	0.23/0.25	8.7

smaller than unity, strengthening the idea of a quasi-isotropy for Fe. In the rest of the samples the H_c/H_k ratio approximates unity.

According to the experimental results the addition of Fe layers increases the coercivity. In all cases according to the experimental results the repeated nucleation of Fe grains leads to an increase of coercivity and these values are close at both interfaces.

Samples 7–9 are sandwiches with a nonmagnetic intermediate layer. XRD analysis indicated a broad diffraction peak with a low intensity identified as bcc Fe(110). The H_k values are similar in these films to those without an intermediate layer from which we may deduce that ferromagnetic coupling between Fe and CoNbZr layers occurs through a nonmagnetic layer up to 60 Å thick. The ferromagnetic coupling also gives a value of magnetization similar to those Fe/CoNbZr alloys. In these samples there is a substantial increase in coercive force indicating a less strong coupling

between the ferromagnetic layers. In these cases a contribution to the coercive force may arise from pinning of the wall at the interfaces.

CONCLUSIONS

To summarize, TBIS measurements by MOKE give an indication of anisotropy field and different local fluctuations of magnetization over the sample in the case of polycrystalline Fe/CoNbZr and Fe/Ag/CoNbZr sandwiches. $\chi_{t,\beta}^{-1}$ vs H has been found to be sensitive to small changes of the dispersion and the quality of the dispersion and XRD and H_c results agree with results found by TBIS measurements.

Low-energy ion beam-assisted deposition of giant magnetoresistive thin films

S. J. Guilfoyle, R. J. Pollard,^{a)} and P. J. Grundy

Joule Laboratory, Department of Physics, University of Salford, Salford M5 4WT, United Kingdom

Granular and multilayer Co-Ag and NiFe-Ag thin films have been prepared by magnetron sputtering and by concurrent low-energy (0–500 eV) ion radiation-assisted deposition. The ion beam bombardment slightly increased the giant magnetoresistance of granular films and then progressively decreased it. X-ray data revealed a change in the crystalline structure of these films, dependent on the energy of the beam. Examination using transmission electron microscopy (TEM) also highlighted differences between the as-sputtered and the ion beam-assisted films. For multilayer films, TEM and x-ray analysis shows changes in the interfacial and crystal structure induced by the ion beam. © 1996 American Institute of Physics. [S0021-8979(96)66908-4]

I. INTRODUCTION

Since the discovery of giant magnetoresistance (GMR) in antiferromagnetically coupled multilayers,¹ there has been intense interest in the electrical and microstructural properties of such films.^{2,3} More recently, GMR has been found to occur in granular systems consisting of a magnetic phase dispersed in a nonmagnetic host.⁴ It is known that for multilayer films the magnetic layer and spacer layer thicknesses are critical for the GMR effect to be maximized.⁵ For the case of granular films, post-deposition annealing and deposition onto heated substrates affect the nucleation and grain size. These conditions also affect the GMR of such films. Therefore, it appears that in a similar way to multilayers, the size and spacing of the magnetic regions strongly influences the GMR in granular samples.

Ion beam-assisted deposition (IBAD) can alter the growth mechanisms and atomic arrangements in thin films. The crystal structure, grain size, resistivity, and surface topography can all be affected by the additional surface energy.⁶ These effects are not necessarily duplicated by thermal treatment such as annealing. Hence, IBAD is a convenient way to explore the dependence of GMR on microstructure in heterogeneous thin films.

II. EXPERIMENT

Films were deposited by magnetron sputtering from separate Co, Ag, and NiFe targets onto precleaned glass and silicon substrates at ambient temperature. Sputter pressures of 3 mTorr and a background pressure of 3×10^{-7} Torr were used. Granular films were approximately 60 nm thick, multilayers were of the order of 90 nm. The ion beam source used was a broad beam Kaufman type, no substrate heating effects from the ion beam were observed. Energies of up to 500 eV were used, with a spread of incident flux between 10^{14} and 10^{15} ions $\text{cm}^{-2} \text{s}^{-1}$, and beam currents of typically 2–3 mA. Samples deposited on glass were cut for electrical measurements and films on silicon were dimpled and ion milled for transmission electron microscope (TEM) examination. All measurements were taken at room temperature.

Composition and thickness details were obtained using a JEOL JSM 6400 scanning electron microscopy (SEM). A JEOL 3010 TEM was used for microstructural examination.

III. RESULTS AND DISCUSSION

Initially a series of Co-Ag and NiFe-Ag granular films was sputtered with concurrent application of the ion beam source at various energies. Straightforward sputtered samples (no IBAD) had compositions 67% Ag and 56% Ag, respectively. All the sputtering conditions remained constant. The GMR values were calculated according to $\Delta\rho/\rho = [\rho_{\text{max}} - \rho(H_{\text{max}})]/\rho(H_{\text{max}})$. For all these samples, the fields applied (2 T) produced GMR loops which were some way from saturation.

Figure 1 shows the variation of the electrical properties ($\rho, \Delta\rho, \Delta\rho/\rho$) with ion beam voltage. There is a slight increase in the GMR for both film types at low energies and a subsequent decrease at higher energies. A possible explanation for the increase is that the additional energy could be causing enhanced surface mobility leading to segregation of the magnetic regions. The resultant size and dispersion of the mag-

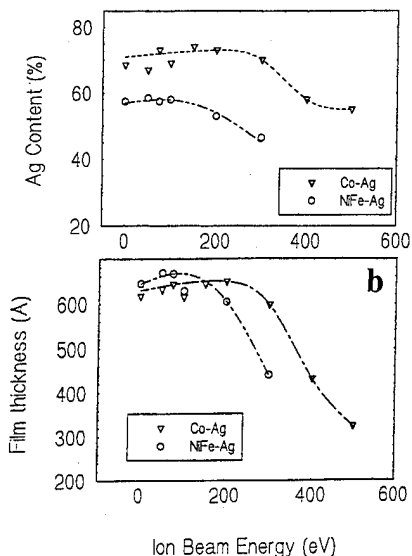

FIG. 2. (a) Ag content and (b) film thickness as a function of ion beam energy.

netic particles would be more suitable for electron scattering. The zero-field resistivity remains virtually constant with energy, implying that significant numbers of extended defects are not being created, which would be the case for thermal treatments such as annealing.

There are several possible reasons why the GMR progressively decreases at higher beam energies. Firstly, the beam may continue to cause growth and segregation, leading to a decreased scattering cross section which is detrimental to the GMR. There is also the possibility of Ar incorporation in the film. Argon atoms could lodge in grain boundaries thus hindering the electron transport properties and growth mechanisms. However, again this is not an important factor as the resistivity has not increased. Finally, the ion beam may preferentially etch the Ag at higher energies, as the sputter yield is significantly higher (approximately 2.8 atoms/ion for Ag and 1.1 for Co at 500 eV, and 0.6 and 1.5 atoms/ion, respectively, at 200 eV).⁷ It is known that GMR is strongly compositionally dependent⁸ so even a small change in the stoichiometry could affect the GMR. Compositional examination using SEM did not detect any significant Ar, though a drop in the Ag content and film thickness (Fig. 2) was highlighted, indicative of preferential sputtering. This compositional change could adequately explain the drop in GMR, though the drop in GMR has been found to be almost independent of film thickness, at least for the thicknesses considered here.⁹ Magnetization curves for films deposited at low energy are generally superparamagnetic in shape with similar M_s values. Increasing the ion beam energy leads to slightly more square loops due to the larger percentage of magnetic material. Preliminary measurements reveal that M_s remains relatively constant for energies less than 150 eV, at higher energies both the NiFe content and the M_s value increase. However, M_s for a film deposited with 500 eV ion beam assistance is significantly less than for a sputtered film with the same composition. This is indicative of a different mag-

FIG. 3. High-angle x-ray ($\text{Cu } K\alpha$) diffraction of Co-Ag granular alloys.

netization process, perhaps the ion beam is affecting the dilution of the magnetic material in the Ag.

X-ray diffraction of a straightforward sputtered Co-Ag film (33% Co) [Fig. 3(a)] using $\text{Cu } K\alpha$ radiation shows only one peak at 38.7° , which corresponds to a d spacing of 2.32 Å. This can be interpreted as that of 111 Ag (2.36 Å) contracted by the presence of the smaller Co atoms. Increasing ion energy causes an increase in the intensity of this peak up to 150 eV [Figs. 3(b)–3(d)]. This correlates with the increase in GMR, as a result of growth and crystallization of Ag grains to form a more ordered structure. Further increasing the beam energy [Figs. 3(e)–3(f)] could hinder strong diffraction by causing some structural imperfections through increased atomic displacements and through the incorporation of impurities in the film. A slight shift (1.5%) towards the bulk Ag 111 d -spacing value was seen at energies above 100 eV, good evidence of elemental segregation.

Electron micrographs of sputtered films reveal a structure consisting of spherical 10–30 nm particles [Fig. 4(a)] whereas IBAD films at higher energies are composed of regions segregated into channels [Fig. 4(b)]. The photograph in Fig. 4(b) is taken from near the edge of the thinned sample. It seems possible from the contrast in the micrograph that the film is amorphous near the Si/film interface. That is, the ion beam is promoting an amorphous metastable structure which crystallizes on segregation.

FIG. 4. TEM micrographs of Co-Ag sample (a) without ion beam assistance and (b) with ion beam (500 eV) assistance.

FIG. 5. High-angle x-ray diffraction of (Fe $K\alpha$) AgNiFe multilayers. Film 1 is as-sputtered, 2 has 2 min of substrate etch at 500 eV, and 3 has been continually ion beam-assisted throughout deposition.

A series of multilayer films [$15 \times (30 \text{ \AA NiFe}, 30 \text{ \AA Ag})$] was deposited from alternately shuttered targets. Film 1 was deposited without ion beam modification. The substrate of film 2 was pre-etched at 500 eV for 2 min. The ion beam was applied at 250 eV during the entire course of deposition (500 s) of film 3 on a pre-etched substrate.

Although these films do not have suitable layer thicknesses for large GMR values, their structural modification is of interest in comparison with that of granular films. Figure 5 shows the high-angle x-ray diffraction (XRD) patterns (Fe $K\alpha$) for these films. Film 1 exhibits a clear Ag(111) peak at 48.5° . There are several other small maxima, one of which corresponds to the bulk NiFe(111) maximum at 56.3° . The peak at 50.1° is likely to be either a (111) satellite maxima, or originates from strained material at the interface of each layer. Further evidence for the superlattice structure is provided by electron microscopy and electron diffraction (to be published). For film 2, the diffracted intensity is slightly reduced, possibly indicating that the ion beam has roughened the substrate, resulting in a less-perfect crystal structure [i.e., a decrease in the preferred (111) texture] and increased scattering defects. This is quantified by a slight increase in the film resistivity. The Ag(111) peak is smaller for film 3, this is as a consequence of the IBA energy being enough to sputter the film, resulting in thinner layers and less material. Also, the superlattice maxima intensity is further reduced for film 3, this could indicate that the constant IBA affects the crystal structure, causing a further decrease in the texture and increased mixing at the interfaces. Initial low-angle measurements (to be published) are commensurate with this.

TEM micrographs of films 1 and 3 are shown in Fig. 6. The multilayer structure of the first film is clearly visible with well-defined NiFe and Ag layers. The orientation of the Ag and NiFe appears to be strongly influenced by the Si

FIG. 6. TEM micrographs of AgNiFe multilayers (a) with and (b) without ion beam assistance. The Si substrate is visible in (a) but not in (b).

substrate, further indication of the superlattice structure. The structure of film 3 is somewhat different. The ion beam appears to have caused layer intermixing, leading to a structure which is reminiscent of the granular materials, with poorly defined layers and little preferred orientation. Further investigation of such materials is underway, including a comparison of this type of film to granular films formed by the annealing of multilayers.

Dynamic hysteresis of two-dimensional magnetic islands with uniaxial anisotropy

C. N. Luse^{a)} and A. Zangwill

School of Physics, Georgia Institute of Technology, Atlanta, Georgia 30332

Frequency-dependent hysteresis for two-dimensional magnetic islands with uniaxial anisotropy is studied with a nearest-neighbor spin-one Ising model in the Bethe–Peierls approximation. A characteristic frequency for magnetization reversal is identified that depends on the island morphology only through the ratio θ/p of the coverage to the mean island perimeter roughness as measured by the density of unsaturated near-neighbor bonds. As a result, dissimilar hysteresis is predicted for large versus small and compact versus fractal islands. © 1996 American Institute of Physics. [S0021-8979(96)67008-7]

Growth-induced surface roughness can influence magnetization processes in ultrathin films in a profound way. Hysteresis measurements of both perpendicular¹ and in-plane² anisotropy systems document this fact and so provide support for the notion that the behavior of magnetic moments at poorly coordinated step and edge sites can control magnetic response if the surface-to-volume ratio is not small. Although quantitative control of the two-dimensional (2D) roughness of an ultrathin film is difficult to achieve, scanning tunneling microscopy studies reveal that one can manipulate the one-dimensional edge roughness of 2D epitaxial islands deposited onto a single-crystal substrate since island size³ and morphology⁴ (fractal versus compact) depend sensitively on growth conditions. This suggests the likely value of a study of the hysteretic response of a collection of 2D magnetic islands deposited on a nonmagnetic substrate at temperatures well below the superparamagnetic blocking temperature. That the requisite magnetic islands can indeed be formed has been demonstrated by Elmers *et al.*⁵ for the Fe/W(110) system.

We report here model mean field calculations of the frequency-dependent hysteresis from a system of 2D islands with specified perimeter-to-area ratio. We assume a strong uniaxial anisotropy (either perpendicular or in-plane) and focus on effects associated with the reduction of the net exchange experienced by edge moments rather than the different anisotropy they experience.⁶ The problem then is equivalent to a spin one Ising model in a time-dependent field with total energy

$$E = -J \sum_{\langle ij \rangle} s_i s_j - H_0 \cos \omega t \sum_i s_i, \quad (1)$$

where J is a nearest-neighbor exchange energy, H_0 measures the external field strength, and the variables $s_i = 0, \pm 1$ label whether the site i of a square lattice is unoccupied or occupied by an atom with spin up or down. The Bethe–Peierls approximation (BPA)⁷ to this system replaces the complex set of N spin variables $\{s_i\}$ by seven quantities: the number densities of single sites occupied by up and down spins: n_+ and n_- , and the number densities of pairs of adjacent sites with all combinations of up spin, down spin, and unoc-

cupied nearest neighbors: n_{++} , n_{--} , n_{+-} , n_{+0} , and n_{-0} . From these, the coverage $\theta = n_+ + n_-$, magnetization density $m = n_+ - n_-$, perimeter density $p = n_{+0} + n_{-0}$, domain wall density $q = n_{+-}$, and island pair magnetization density $g = n_{++} - n_{--}$ are defined and assigned to the components of a vector \mathbf{x} . For $\omega=0$, the BPA yields a well-defined free energy $F(\mathbf{x})$ from which equilibrium properties are obtained by minimization.⁷

To treat $\omega \neq 0$, we adopt a kinetic Bethe–Peierls approximation (KBPA)⁸ and let $\mathbf{x}(t)$ denote the statistical expectation value of the (now) time-varying variable set defined above. The time evolution of each $x_k \in \mathbf{x}(t)$ is determined from

$$\tau \frac{d}{dt} x_k(t) = \sum_{\Delta} \Delta_k \sum_{\mathbf{p} \in \Delta} n[\mathbf{p}|\mathbf{x}(t)] e^{-E(\mathbf{p})/k_B T}, \quad (2)$$

where Δ is a vector of integers that specifies the change $\mathbf{x} \rightarrow \mathbf{x} + \Delta/N$ in the state of the system associated with a spin flip event. An isolated spin is presumed to flip spontaneously in zero field after a mean time τ while the configuration-dependent energy barrier $E(\mathbf{p})$ to flip an arbitrary spin is estimated from the BPA to Eq. (1). The combinatoric factor $n[\mathbf{p}|\mathbf{x}(t)]$ is the BPA to the number density of sites with local arrangements of spins \mathbf{p} compatible with Δ given that the system average is fixed at $\mathbf{x}(t)$. The sum over \mathbf{p} indicates that several spin configurations generally are consistent with a given value of Δ . Our calculations regard the coverage θ and island roughness p as independent free parameters. The remaining variables $m(t)$, $q(t)$, and $g(t)$ are determined from a numerical solution to the coupled nonlinear set (2) using Gear's method⁹ for stiff differential equations. We judge that steady state has been achieved when $|[x_k(t) - x_k(t + 2\pi/\omega)]/x_k(t)| \leq 10^{-5}$ for all three variables and compute hysteresis loop areas from $m(t)$ and $H(t)$ using the formula $A = \oint m dH$. All the results reported here use the fixed values $J/k_B T = 1.0$ and $H_0/k_B T = 1.5$.

To appreciate the origin of static hysteresis in this model, the inset to Fig. 1 shows the BPA free energy as a function of m at $H=0$ and low temperature. Application of a field $+H_0$ tips the curve so that the absolute minimum occurs at the saturation magnetization $+m_0$. The curve rocks to the left and $-m_0$ eventually becomes the absolute minimum as the field is reduced and then reversed adiabatically. A square hysteresis loop results because the magnetization

FIG. 1. Scaled hysteresis loop areas plotted vs scaled frequency for several values of θ/p . Different choices of θ and p yield curves exactly coincident with those shown so long as their ratio is fixed. The filled circles are experimental data for Co/Cu(001) from Ref. 10. Inset: effective BPA free energy $F(m|H)$ when $H=0$. The parameters δ and m_0 vary with θ and p . The text discusses the instantaneous magnetization (black dot) as a Newtonian particle that slides along this curve.

takes the final abscissa value of a classical particle that slides down to the nearest local minimum of this energy curve. In fact, the barrier between the two minima in Fig. 1 is an artifact of the mean field approximation and there is no true thermal activation. We thus are free to *reinterpret* the asymmetric double-well structure of $F(m|H)$ as arising from the presumed uniaxial anisotropy well below the superparamagnetic blocking temperature. Any change in "temperature" in Eq. (2) merely renormalizes H_0 and the magnitude of an effective anisotropy constant related to J . In this language, all the effects we report below arise from the parametric dependence of the BPA free energy on the coverage and perimeter density.

Figure 1 shows normalized loop areas $A(\omega)$ calculated for several values of the ratio of the coverage θ to the edge roughness p for our problem along with Kerr-effect data of Jiang *et al.*¹⁰ for ~ 3 monolayers of Co/Cu(001). The agreement may well reflect the fact that the top of an as-grown ultrathin magnetic film is well described as a collection of two-dimensional islands. But each theoretical point on this diagram corresponds to results obtained from many different choices of θ and p . That is, the curves of $A(\omega)$ are identical so long as the ratio θ/p is held fixed. The latter thus can be chosen to parameterize both the shape of the curves and the value of the frequency ω_0 at which the loop area maximum occurs (Fig. 2).

At fixed coverage, the calculated loop areas exhibit a nontrivial dependence on p (Fig. 3) for different values of the frequency. The static loop area (see caption for frequency labeling) decreases with increasing roughness and vanishes above a coverage-dependent critical value of perimeter density p_c . $A(p) > 0$ and is monotone decreasing at the lowest frequencies but develops a simple maximum as the frequency increases. At still higher values of ω , a discontinuity appears in $A(p)$ that eventually evolves to a cusp singularity.

FIG. 2. Calculated dependence of the dimensionless resonant frequency $\omega_0\tau$ on the scaling parameter θ/p (solid curve). Dashed line is drawn at $\omega\tau=0.3$.

At the largest frequencies investigated, the cusp occurs precisely at p_c and $A(p)$ is composed of two parabolic arcs.

To interpret these results, it is useful to regard the frequency response of the amplitude and phase of the magnetization $m(t)$ with respect to the magnetic field $H(t)$ as analogous to the corresponding quantities for the displacement of a damped, driven oscillator with respect to its driving force. So long as $\omega < \omega_0$, the magnetization makes large amplitude excursions between the two minima at $\pm m_0$ in Fig. 1. One checks that the loop area increases in this regime simply because the phase of $m(t)$ progressively lags the phase of $H(t)$ as ω increases. The area is maximal at $\omega = \omega_0$ when the phase lag is $\pi/2$ and decreases thereafter as the excursions of $m(t)$ from zero become smaller and smaller with increasing frequency.

FIG. 3. Calculated hysteresis loop areas $A(p)$ at $\theta=1/2$ plotted versus perimeter density p for different values of dimensionless sweep frequency $\omega\tau$. Beginning at the bottom of the figure at $p=1$ and moving upward in order, the curves labeled with open symbols correspond to $\omega\tau$ values of 0.0 (circles), 0.03 (triangles), 0.1 (triangles), 0.3 (circles), and 0.5 (squares). Beginning at the top of the figure at $p=1$ and moving downward in order, the curves labeled with closed circles correspond to $\omega\tau=1.0, 2.0, 5.0$, and 10.0.

The resonant frequency ω_0 can be identified with the inverse of the characteristic time for the 'particle' in the inset to Fig. 1 to slide from the unstable maximum to one of the minima of the effective free energy. The variation of ω_0 depicted in Fig. 2 then suggests that either δ or m_0 or both decrease as θ/p decreases. To connect this notion more directly with the surface morphology, we offer two alternative spatial interpretations of our mean field theory. Consider a two-dimensional island composed of S atoms. The fractal dimension d_f and perimeter dimension d_p of the island are defined by the relations $S \propto R^{d_f}$ and $P \propto R^{d_p}$, where R is the radius of a circle that completely encloses the island and P is the total number of perimeter atoms. It follows that $R^{d_f-d_p} = \theta/p$ and $N = \theta/R^{d_f}$, where N is the total island number density. Now suppose the total coverage is held fixed. For compact islands, the resonant frequency decreases monotonically as the average island size increases. Alternatively, for fixed θ and fixed N , the resonant frequency increases monotonically as the fractal character of each island increases. In either case, the value of ω_0 correlates with the average coordination number of occupied lattice sites.

This idea is sufficient to develop a qualitative understanding of the behavior seen in Fig. 3. The magnetization $m(t)$ is nearly π out-of-phase with $H(t)$ at the highest frequencies where ω is larger than any value of ω_0 . The details of the effective potential are not important in this regime, but the mere fact that $d\omega_0/dp > 0$ (so that $\omega - \omega_0$ decreases) guarantees that $dA/dp > 0$ since the phase shift, in turn, retreats toward $\pi/2$. The latter is achieved when $\omega = \omega_0$ so $A(p)$ exhibits a maximum whenever a horizontal line drawn at the sweep frequency ω intersects the curve in Fig. 2. Of course, $m(t)$ and $H(t)$ are nearly in-phase when ω is smaller than any value of ω_0 and the smallest loops will arise when δ and m_0 are minimal. The fact that this occurs for maximal edge roughness (so that $dA/dp < 0$) is most clear from the static case since the BPA to the Ising model⁷ exhibits no spontaneous magnetization for coordination numbers less than two.

The discontinuity and kink features are a bit more subtle. Suppose the relevant feature occurs at the frequency dependent value p_0 . It turns out that the hysteresis loops at fixed ω are asymmetric, i.e., centered about a nonzero value of magnetization, for all $p < p_0$ but are symmetric with respect to

$m=0$ for all $p > p_0$. The "capture" of $m(t)$ in one well (asymmetric case) is not unreasonable since the discontinuity/kink anyway occurs only when $\omega \gg \omega_0$ and the total excursion of $m(t)$ is not large. The decrease in δ that accompanies increased edge roughness then makes the "escape" of the magnetization (symmetric case) readily explicable if not its signature as a nonanalyticity in $A(p)$.

In conclusion, we have presented the results of Bethe–Peierls-type mean field calculations for the dynamic magnetic hysteresis expected from a collection of two-dimensional islands after deposition onto a nonmagnetic substrate. The islands are assumed to be superparamagnetic and maintained at low temperature so that thermal magnetization reversal does not occur. The frequency-dependent loop areas and resonant frequencies were found to depend only on the ratio of the coverage to the mean island perimeter density in this approximation. The systematic variations we predict are amenable to direct experimental test because variations in substrate temperature and deposition flux permit (nearly) independent control of both the total island number density and the island edge roughness.

M. Naoe

Faculty of Engineering, Tokyo Institute of Technology, Oh-okayama, Meguro-ku, Tokyo 152, Japan

Uniaxial magnetic anisotropy induced in iron thin films by the oblique incidence of deposition particles was investigated by computer simulation. In the simulation, the self-shadowing effect was considered mainly to explain changes in the magnetic anisotropy of iron films with the incident angle. The simulated grain shape in the film changes significantly with the incident angle of deposition particles. Grains elongated in a direction normal to the incidence direction of depositing particles were clearly observed in simulated film deposited with an incidence angle around 60° . However, the film deposited at an incidence angle of 80° had columnar grains separated from each other and inclined to the incidence direction. Changes in the uniaxial magnetic anisotropy of the film can be qualitatively explained by the shape anisotropy of these grains in the film. The decrease in saturation magnetization of these films with incident angle seems to be mainly caused by the formation of a porous film. © 1996 American Institute of Physics. [S0021-8979(96)67108-6]

I. INTRODUCTION

Many reports on the computer simulation of microstructures in film treated by the oblique incidence of deposition have appeared in the literature.¹⁻¹² The formation of inclined columnar structures in film is mainly caused by the self-shadowing effect in growing films.

It is well known that iron film deposited by the oblique incidence of particles has in-plane uniaxial magnetic anisotropy^{13,14} and its easy axis changes from the normal to the parallel direction of incidence particles as incident angle increases from 60° to 80° .¹³ These changes in the direction and energy of magnetic anisotropy are thought to be caused by changes in the microstructure of the film due to the incident angle of deposition particles.^{2,4,13,14} However, it was still not clear how the grain structure in the film plane changes with the incident angle of particles as a result of the self-shadowing effect, since the dimensions of simulated film used were too small. In this study, we investigated the self-shadowing effect on the in-plane microstructure of the film by using three-dimensional Monte Carlo simulation based on a simple hard sphere model that showed that changes in the uniaxial magnetic anisotropy of iron film with an incident angle were mainly caused by changes in the grain shapes in the film.

II. SIMULATION MODEL

In this study, a Monte Carlo simulation model similar to the one Henderson *et al.* reported¹ were used, e.g., we assumed that the depositing atoms were hard spheres and allowed to relax to the extent that each moved to the nearest position where it was able to make contact with three atoms (zero migration case). The direction of incidence of depositing atoms on the substrate was in the x - z plane as shown in Fig. 1. In the calculation, atoms with a radius 1.26 \AA were deposited on a $725 \text{ \AA} \times 725 \text{ \AA}$ substrate. Although the total

lack of relaxation in the adatom was not physically realistic, it was set at a limit where the self-shadowing effect became the most pronounced.

When the migration of the adatom was taken into consideration, incident atoms migrated across the surface jumping from site to site as shown in Fig. 1. When the adatom reached a site where it contacts with more than four atoms during migration, the adatom was assumed to be fixed in that position.

III. RESULTS AND DISCUSSION

It is well known that the uniaxial magnetic anisotropy of iron thin films deposited by the oblique incidence of particles changes significantly with the incidence angle as shown in Fig. 2.¹³ Films deposited at an incidence angle below 70° have uniaxial magnetic anisotropy with its easy axis normal

FIG. 1. Hard sphere deposition model used in this study. Adatom migration length was changed as shown in the figure.

FIG. 2. Changes in uniaxial magnetic anisotropy energy K_u of iron film with incidence angle reported by West (Ref. 13).

to the direction of incidence. However, films deposited at an incidence angle above 80° have uniaxial magnetic anisotropy with its easy axis parallel to the plane of incidence.

Figure 3 shows the film structures: (a), (c), (e): cross section [parallel to plane of incidence (x - z plane)] and (b), (d), (f): in-plane section [parallel to substrate (x - y plane)]

FIG. 3. Structures of simulated films produced at incidence angles 0° : (a), (b), 60° : (c), (d), and 80° : (e), (f). (a), (c), and (e) are cross sections of the film parallel to the plane of incidence (x - z plane) and (b), (d), and (f) are in-plane sections parallel to the substrate (x - y plane).

FIG. 4. Changes in grain shapes L_x/L_y with incidence angle, where L_x and L_y are mean grain size in x and y direction, respectively.

calculated for various oblique incidence angles of deposited particles. In calculation, surface migration of deposited atoms was not considered. It is evident from the figure that films deposited at an oblique angle around 60° have clear elongated grains. This grain can create large uniaxial shape magnetic anisotropy in film with its easy axis normal to the incident direction of deposited particles. To clarify how changes in grain shape are related to incident angle, the ratio of L_x to L_y was calculated, where L_x and L_y were mean grain size in the x and y directions, respectively. Figure 4 shows changes in the L_x/L_y ratio with incidence angle α . It is clear from the figure that ratio L_x/L_y assumes a minimum value at an incidence angle around 60° . This indicates that elongated grains in the y direction were formed in the film. This result can be explained as follows: grains in the film lose continuity in the parallel direction much more easily than in the normal direction to the incident direction of particles, since the shadow region for depositing particles only expands in a direction parallel to the plane of incidence. Therefore, increase in uniaxial magnetic anisotropy energy with increase in incidence angle α from 0 to 60° is due to the formation of elongated grains shown in Figs. 3(c) and 3(d).

Further increases in incident angle causes the shadowing region on the film surface to extend greatly so that the continuity of grains even in the normal direction will be lost due to the self-shadowing effect. As a result, film deposited at an

FIG. 5. Changes in saturation magnetization $M_s/M_s(0)$ of iron films with incidence angle reported by Hashimoto *et al.* (Ref. 14). Changes in density $\rho/\rho(0)$ of simulated films with incidence angle are also shown.

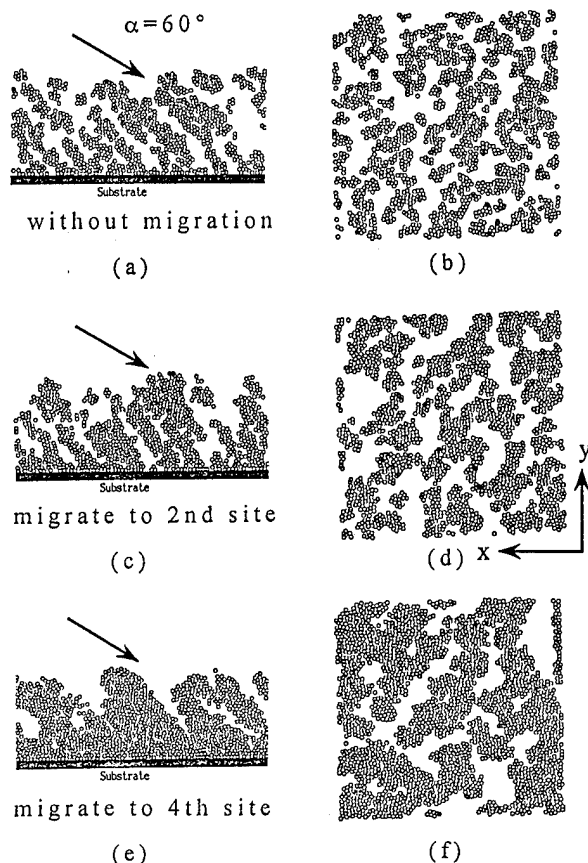

FIG. 6. Simulated films structures produced at incidence angle of 60° for three kinds of adatom migration length [(a)(b): fixed at first site, (c)(d): fixed at second site, and (e)(f): fixed at fourth site as shown in Fig. 1].

incidence angle of 80° is composed of inclined columnar grains that are separated from each other as shown in Figs. 3(e) and 3(f). This kind of film structure induces uniaxial magnetic shape anisotropy with its easy axis parallel to the plane of incidence of deposition particles.

A change in saturation magnetization M_s of iron films with the incidence angle shown in Fig. 5 was reported by Hashimoto *et al.*¹⁴ Changes in density in the simulated film due to incidence angle are also shown in Fig. 5. M_s and density decreases in similar manner with incident angle. This suggests that the decrease in M_s of iron film due to incidence angle was mainly caused by a reduction in film density.

Figure 6 shows simulated film structures calculated for various surface migrations of deposited adatoms. It is clear from the figure that both film density and grain size increase monotonously as surface migration increases. The grain shape in the x - y plane (L_x/L_y ratio), however, barely changes when the migration length of the deposition particle increases from two to four steps.

IV. CONCLUSIONS

To explain uniaxial magnetic anisotropy induced in iron films deposited by oblique evaporation, film structures were simulated using Monte Carlo simulation by depositing atoms on a $725 \text{ \AA} \times 725 \text{ \AA}$ substrate. In the simulation, the self-shadowing effect was the only mechanism responsible for formation of voids in the film. The shape of simulated grain in the film changed significantly with the incident angle of deposition particles. Changes in the uniaxial magnetic anisotropy of the film deposited by oblique incidence can be qualitatively explained by changes in the shape anisotropy of these grains in the film. The decrease in saturation magnetization of iron film due to the incident angle agreed well with the decrease in film density. Therefore, the self shadowing effect is the most important mechanism causing uniaxial magnetic anisotropy in iron film deposited by oblique evaporation.

Complex anisotropies in sputtered $\text{Co}_{90}\text{Fe}_{10}$ alloy thin films (abstract)

E. J. Yun, W. Win, and R. M. Walser

I/UCR Center for Magnetism, The University of Texas at Austin, Austin, Texas 78712

Among all the known magnetic materials with vanishingly small magnetostriction, alloys with the composition $\text{Co}_{90}\text{Fe}_{10}$ have the highest magnetization at 300 K. Despite this combination of useful properties, thin films of these alloys have been little studied. This study investigated the magnetic characteristics of $\text{Co}_{90}\text{Fe}_{10}$ alloy thin films deposited by rf diode sputtering. The hysteresis loops of nominal 1000-Å-thick $\text{Co}_{90}\text{Fe}_{10}$ films deposited in ≈ 150 Oe planar field exhibited complex biaxiality. Two, orthogonal easy axis loops with different coercivities were observed. The direction corresponding to the hysteresis loops with the smallest (largest) coercivity are referred to as the soft (easy) axis. Dual hard axes were found at $\pm 68^\circ$ on either side of the easy axis. Similar biaxial hysteresis loops were observed in $\text{Co}_{90}\text{Fe}_{10}$ films deposited by sequential sputtering from pure Co and Fe targets on static or rotating substrates, and in films deposited from a $\text{Co}_{90}\text{Fe}_{10}$ alloy target on stationary substrates. The magnetization and resistivity of the sequentially sputtered films were 19.66 kG and $18.4 \mu\Omega \text{ cm}$, while those deposited from the alloy target were 19.00 kG and $14.5 \mu\Omega \text{ cm}$. The biaxiality was sensitive to a number of parameters which appeared to destabilize the soft axis state compared to the hard axis states. With increasing film thickness (to 3400 Å), the biaxiality disappeared, and films deposited under similar conditions exhibited rotatable anisotropy. The biaxiality could also be reduced, and the coercivity increased, by increasing the magnetic bias applied during deposition. Films annealed at 370°C became uniaxial when a 1.3 kOe field was applied parallel to the easy axis, and became isotropic when the field was parallel to the hard axis. The biaxiality was enhanced, and H_c reduced, by depositing 1000-Å-thick $\text{Co}_{90}\text{Fe}_{10}$ films onto a 500 Å 80Ni20Fe underlayer. In all cases, whenever the biaxiality was eliminated, the films exhibited a rotatable uniaxial anisotropy. The biaxiality of these films likely has its origin in the coupling of two uniaxial anisotropies as previously analyzed.¹ The deposited films are highly polycrystalline. In addition, the symmetries of the planar magnetic state obtained were the same for crystalline and amorphous substrates. Thus, it is unlikely that either uniaxial anisotropy is due to magnetocrystallinity, but are probably induced. The experimental trends observed in the study can in principle be understood in terms of a two layer model in which a rotatable, stress induced uniaxial anisotropy in an underlayer, is exchange coupled to the field induced uniaxial anisotropy of an overlayer. In this model the complex biaxiality is modified by experimental parameters which modify the relative strength and coupling strength of these anisotropies. © 1996 American Institute of Physics. Ferromagnetic resonance studies of noble metals based sandwiches

Y. D. Wang, L. Y. Chen, Y. X. Sui,^{a)} S. M. Zhou, Y. Wang, Y. X. Zheng, Y. H. Qian, and Q. Y. Jin

T.-D. Lee Physics Laboratory and Department of Physics, Fudan University, Shanghai 200433, People's Republic of China

In this paper we have prepared Fe/Cu, Ag, Au/Fe sandwiches by ion beam sputtering and studied the interlayer coupling behavior by ferromagnetic resonance technique. In these sandwiches the Fe and noble metal layers are polycrystalline in the textures of (110) and (111), respectively. It is found that the in-plane resonance field and the linewidth oscillate as a function of nonmagnetic layer thickness in a period of about 1.0 nm for Fe/Cu, Au/Fe structures, and 1.4 nm for Fe/Ag/Fe system. It is suggested that the interlayer coupling strength between the ferromagnetic layers oscillates in the same period with the resonance field. An in-plane anisotropy was found in Fe/Ag/Fe system.

© 1996 American Institute of Physics. [S0021-8979(96)67208-1]

I. INTRODUCTION

The interlayer coupling between ferromagnetic layers separated by nonmagnetic metal spacer layers has attracted much attention because of its importance in basic research and in applications. For example, the antiferromagnetic coupling can induce giant magnetoresistance.¹ Because the Fermi surfaces for Cu, Ag, and Au are simpler and similar to each other they are usually used as spacer layers.² Furthermore, many experiments have shown that the noble metal based multilayers can exhibit large magnetoresistance changes.¹ For sandwich structures, many methods have been employed to investigate the interlayer coupling behavior, such as ferromagnetic resonance (FMR),³ Brillouin light scattering,⁴ surface magneto-optical Kerr effect (SMOKE),⁵ magnetoresistance (MR), and vibrating sample magnetometer. With FMR technique, both the strength and the sign of the interlayer coupling can be known. Moreover, it is usually used to study the anisotropy in layered structures. In this paper we will study the interlayer coupling behavior in Fe/Cu, Ag, Au/Fe sandwiches with FMR technique. It is interesting to find that the in-plane resonance field and the linewidth oscillate as a function of nonmagnetic layer thickness.

II. EXPERIMENTS AND DISCUSSIONS

All samples were deposited onto Si(100) slices by ion beam sputtering technique from iron, copper, silver, and gold targets with an area of $8 \times 10 \text{ cm}^2$, in the structure order of X(1.0 nm)/Fe(4.0 nm)/X/Fe(4.0 nm)/X(10.0 nm)/Si, where X refers to Cu, Ag, and Au, respectively. The top layer was used to avoid oxidation. The background pressure was $7 \times 10^{-5} \text{ Pa}$ and the Ar pressure $2 \times 10^{-2} \text{ Pa}$ during deposition. The deposition rates of Fe, Cu, Ag, and Au were 0.08, 0.15, 0.18, and 0.15 nm/s, respectively. The layer thicknesses were controlled through the rotation of target holder and shutters by a microcomputer. X-ray diffraction showed that for these samples the Fe and noble metal layers are polycrystalline in the textures of bcc (110) and of fcc (111), respectively.

The electronic paramagnetic resonance spectrometer of model ER-200D-SRC was used to measure the room-temperature FMR spectra with a microwave frequency of 9.78 GHz under an applied magnetic field parallel to the film plane.

As shown in Figs. 1 and 2, for Fe/Cu/Fe and Fe/Au/Fe structures the resonant field H_{res} in the parallel geometry showed oscillation as a function of nonmagnetic layer thickness with a period of about 1.0 nm, for Fe/Ag/Fe system the period is 1.4 nm, as presented in Fig. 3. The resonance linewidth ΔH also oscillates in the same period as the resonance field. According to theoretical model proposed by Cochran *et al.*⁶ it can be considered that the oscillation of H_{res} is due to the interlayer coupling oscillation. In fact, the oscillation of the resonant field might be produced by the oscillation of anisotropy energies due to interface effect. The interface effect originates from the interlayer coupling. So we can suggest that the oscillation of the resonant field is a result of the oscillation of the interlayer coupling strength. Moreover, the oscillation of the resonance field has also been observed in Fe-Ni/Cr/Fe-Ni systems⁷ and the correlated oscillations between the resonance field and the linewidth have been also observed in previous work about Fe-Ni/Cu multilayers by

FIG. 1. The d_{Cu} dependence of the resonance field H_{res} and the resonance linewidth ΔH in the parallel geometry for Fe(4.0 nm)/Cu/Fe(4.0 nm) sandwiches.

FIG. 2. The d_{Au} dependence of the resonance field H_{res} and the resonance linewidth ΔH in the parallel geometry for Fe(4.0 nm)/Au/Fe(4.0 nm) sandwiches.

FIG. 4. The angle dependence of the in-plane resonance field in the range of 0–180° for Fe/Ag/Fe sandwiches, which begins at an arbitrary position.

Zhou *et al.*⁸ They were all attributed to the oscillatory inter-layer coupling strength.

In the early stages, the oscillatory coupling was explained as a RKKY-like interaction. Recently several studies showed that the quantum well states exist in noble metal films deposited on ferromagnetic substrates,⁹ that is to say, the s, p -like quantum well states in Cu, Ag, and Au layers were found by the inverse photoemission in Cu, Ag, or Au/Fe structures. The spin-polarized quantum well states in noble metal layers have been proposed to be carriers of the oscillatory interlayer coupling.^{10–13} For the quantum well states, the oscillation period $\Lambda = \pi/|k_F - k_{\text{BZ}}|$, where k_F and k_{BZ} are wave vectors on the Fermi surface and at the FBZ in the oriented normal direction in nonmagnetic layers. For Cu, Ag, and Au in the texture of (111), Λ is found to be 0.95, 1.4, and 1.0 nm.² It is obvious that the observed oscillation periods in the above series of sandwiches are close to the corresponding calculated data. It is noted that the interface roughness acts as a low-pass filter for the oscillation frequency¹⁴ and does not play any role on the long oscillation period for (111) direction of Ag layers. In addition to the resonant field,

for above structures the polar Kerr rotation and ellipticity were also observed to oscillate respectively in a same period as the resonant field with the variation of the nonmagnetic layer thickness, which will be discussed elsewhere.

We have also studied the behavior of the in-plane anisotropy in Fe/Ag/Fe structures. As shown in Fig. 4 the resonance field has a maximum in the angle range of 180°. This in-plane anisotropy might depend on the condition in sputtering process, including the energies of Ar^+ and incident angle. However this parameters influence the anisotropy needs further detailed work.

In conclusions, we have prepared three series of Fe/Cu/Fe, Fe/Ag/Fe, and Fe/Au/Fe sandwiches by ion beam sputtering and studied the interlayer coupling behaviors with FMR technique. It is interesting to find that for these samples, the in-plane resonant field and the linewidth oscillates with the same periods of 1.0, 1.4, 1.0 nm, respectively. It is suggested that the interlayer coupling oscillates in strength as a function of nonmagnetic layer thickness.

Finite temperature magnetization reversal in ultrathin magnetic films

S. T. Chui

Bartol Research Institute, University of Delaware, Newark, Delaware 19716

We study the magnetization reversal of Heisenberg spins in a two-dimensional plane under an external reversing field at finite temperatures. In the Ising limit dominated by uniaxial anisotropy and exchange, we observe nucleation of domains in Monte Carlo simulations. Analysis of the probability distribution in the energy provides for an estimate of the free energy for domain nucleation that is much smaller than that obtained from the wall energy at zero field because the energy of the nucleus approaches zero at the threshold of coherent rotation. The coercive field depends linearly on the temperature. When the dipolar interaction becomes important, reversed spins domains form quickly but do not grow. There is an intermediate regime when most spins are aligned parallel to the plane. © 1996 American Institute of Physics. [S0021-8979(96)67308-4]

Stimulated by the possibility of integrating the semiconductor microelectronics technology with magnetic elements¹ there has been much interest recently in understanding the fundamental physics of magnetic films from 1 to 100 layers.² Depending on material parameters, the magnetization can lie parallel or perpendicular to the plane.^{3,4}

A question of importance is how the spins reverse itself under the presence of an external field. This issue has been much studied at zero temperature in "thick" films⁵ but very little work was done at finite temperature in ultrathin films where nucleation of domains through thermal fluctuation becomes possible.

In this article we study the magnetization reversal of Heisenberg spins in a 2D plane interacting with long-range dipolar, short-range exchange, and uniaxial anisotropy (perpendicular to the film) interactions at finite temperatures. In real systems, impurity⁶ and edge effects can also be important. To elucidate the physics of this complex phenomenon it is important to understand one effect at a time. For this reason impurity and edge effects are not considered in this paper. Our results provide for new physical pictures in this largely unexplored area and are summarized in the abstract. We now describe our results in detail.

We choose our coordinates so that the film is in the xy plane. The total energy of the system is $E_T = E_0 - H \sum_i S_{zi}$, where the "internal" interaction energy between the spins is $E_0 = 0.5 \sum_{ij=xyz, RR'} V_{ij}(R-R') S_i(R) S_j(R')$. The sum is over the 2D positions R, R' of the spins in the plane. The potential $V = V_d + V_e + V_a$ is the sum of the dipolar energy $V_{dij}(R) = g(\delta_{ij}/R^3 - 3R_i R_j/R^5)$; the exchange energy $V_e = -J \delta(R-R'+d) \delta_{ij}$, and the anisotropy energy $V_a = -2K \delta(R-R') \delta_{iz} \delta_{jz}$. Here d denotes the nearest neighbors. The simulation reported here follows our earlier work on the equilibrium finite temperature studies of the phase diagram in ultrathin magnetic films,³ where $H=0$. The long-range dipolar potential is summed with the Ewald sum technique. In the present study, we start with the magnetization upward along the z direction and study the system in the presence of a reversing magnetic field. We have assumed that we are dealing with block spins^{4,5} with renormalized couplings so that the formation of domains can be observed in a reasonable size system.

We first describe our results in the Ising-like limit (g

$= 0$). For experimental films involving rare-earth elements the site anisotropy is large. This Ising limit is a reasonable approximation. In Fig. 1 we show a typical intermediate Monte Carlo configuration which clearly demonstrates the spin reversal through domain formation. An estimate of the coercive field can be determined from the threshold at which nucleation occurs during the finite simulation time (2000 MC steps/spin).

An estimate of the free energy of nucleation ΔF can be obtained from the total number of configurations, $P(E_0, t)$, of different "internal" interaction energy E_0 accumulated from the initial time up till time t . This "probability distribution" accumulated till a time near the completion of the magnetization reversal is illustrated by the dashed line in Fig. 2 for $J = -2$, $K = -1$, $g = 0$. The normalization of P is arbitrary. Since E_0 does not include contributions due to interactions with the external field, increasing E_0 corresponds to increasing domain wall length. As time increases and domain walls are formed, E_0 is increased. Thus different E_0 corresponds to different times where the contributions to the total accumulated distribution are generated. The peak at around $E_1 = 549$ corresponds to configurations where domains are absent and most of the spins are lined up, as we can see from the fact that the average z magnetization $|M_z(E_0)|$, shown as the dotted curve in Fig. 2, is still close to

FIG. 1. The orientation of the spins with respect to the z axis (the vertical direction shown) for an Ising-like system near the threshold for coherent rotation at an intermediate time. The location of the spins are in the xy plane. The orientation of the spins here is not in the xy plane. The xy orientation of the spins is not shown.

FIG. 2. Probability distribution $P(E_0)/2 \times 10^5$, the total energy $E_T/2 \times 10^4$ and the absolute value of the average magnetization as a function of E_0 for an Ising-like system.

one. These configurations occur at the early history of the reversal process. As time increases eventually a critical nucleus is formed near $E_2 \approx 568$, where $P(E_2)$ is at a minimum. As the domain grows, the domain wall length is increased and E_0 increases. At the same time the net magnetization in the z direction decreases. This metastable phase with a domain corresponds to the second smaller peak around 580. Eventually when all the spins are reversed another peak corresponding to the final state develops. This occurs at an energy of 480 and is not shown in this figure. From Boltzman's distribution, we expect $P(E_1)/P(E_2) = \exp(-\Delta F/kT)$. We thus estimate the free energy of nucleation by $\Delta F = T \ln[P(E_1)/P(E_2)] \approx 1.5$ in units with $k=1$. The total energy, which includes that of the external magnetic field, is shown by the solid line.

The nucleation energy from conventional theory is $E_n = \pi\tau^2/2H$, where τ is the domain wall energy per unit length. We estimated τ at zero field numerically¹⁰ and found that $E_n \approx 50$, much larger than ΔF .

When $H > H_r = 2K$, the spins can be reversed by coherent rotation so that all the spins rotated together as a whole. The formula for the nucleus and the domain wall energy discussed in the previous paragraph is derived in zero magnetic field. When the field is included, near the threshold for coherent rotation τ approaches zero as $\tau \propto (H - H_r)^{2.7-9}$. Thus at finite temperatures coherent rotation is always preceded by nucleation. When the nuclei first formed the spins inside are only rotated by an angle θ_F of the order $\cos^{-1}[(H - K)/K]$. The sum of the anisotropy energy and the magnetic field energy is approximately the same at θ_F and at $\theta=0$.

An intermediate configuration close to the onset of coherent rotation ($K=1$, $H=1.9$, $T=0.15$) is illustrated in Fig. 1. There is large scale fluctuation where the spins are tilted slightly. In addition we also see three nuclei at the upper left, lower right, and lower middle. For the nuclei in the lower middle the spins are not completely rotated inside. As we discussed earlier this is the rule for small nuclei. Inspection of an earlier configuration shows that when the nu-

FIG. 3. The coercive field as a function of temperature for $J=4$, $K=2$, and $g=0$.

clei at the upper left and lower right first formed, the spins inside them are not completely rotated either.

In Fig. 3 we show the temperature dependence of the coercive field for $J=4$, $K=2$, and $g=0$. H_c depends approximately linearly on T . This is in contrast with the case of small particles where one expects a temperature dependence of the form $\sqrt{1-T/T_B}$ for some constant T_B . This linear temperature dependence can be understood as follows. The energy of a nucleus consists of a sum of a wall energy and an interior contribution. We expect the interior contribution to be small because, as we argued above, in the interior the spins have only turned by a small amount θ_F and their energy change is small. The domain wall energy consists of a sum of two parts: the wall bending energy and the energy per unit length τ for flat walls. Thus the wall energy of a circular nucleus of radius R is approximately $E_n = \tau 2\pi R + \beta/R$ for some elastic constant β . We optimize E_n with respect to R and get $R = \sqrt{\beta/2\pi\tau}$. For the small particle case, the size of the nucleus is not a function of H . In the present case, it is. Substituting this value of R into E_n , we obtain a nucleation energy $E_n \approx 2\sqrt{2\pi\tau\beta}$. At a finite temperature the nucleation energy is comparable to the temperature at the coercive field, i.e., $E_n = \gamma T$ for some constants γ of the order of unity. Recall that $\tau \propto (H - H_r)^2$. Substituting in the value of E_n , we obtain a linear temperature dependence for the coercive field. We next turn our attention to the case where the dipolar interaction is no longer zero.

Monte Carlo simulations were carried out with a nonzero dipolar interaction. A typical configuration is displayed in Fig. 4 where we show the projection of the spin on the xy plane at an intermediate time for $J=-2$, $K=-1$, $g=-0.1208$, $T=0.4$, $h=0.7$. There are now intermediate configurations where nearly all the spins are along the xy plane with pockets of spin rotated domains (empty-like spaces) in between. The reversal mechanism seems different from the Ising case.

Examination of histories of spin configurations indicates that the pockets of spin down domains form very quickly. When all spins are along the z axis, the uniaxial anisotropy is reduced by the dipolar interaction to $K' = K - g/g_1$, where $1/g_1 = 0.75 \sum_R 1/R^3 = 0.128$.³ The energy to create a domain wall is reduced from \sqrt{KJ} to $\sqrt{K'J}$. Thus it becomes easier to create spin down domain. The domain wall width is now increased to $\sqrt{J/K'}$. When the pockets of spin down domains

FIG. 4. The projection of the spins interacting with an additional dipolar interaction onto the xy plane $\sin \theta (\cos \theta, \sin \theta)$ at an intermediate time. The orientation of the spins shown are in the same plane as the location of the spins. This is different from Fig. 1.

are created, the domain walls from different nuclei now overlap so that there is a large fraction of spins along the xy plane. When this happens, the effective anisotropy field is no longer K' but is increased back up to close to K . Also, it becomes more difficult for the spin reversed domains to grow because the local dipolar field created by the other spins in the xy plane make it more difficult to flip the spins at the boundary from the xy plane to the negative z direction. Thus the spins along the xy plane remain locked in. Instead the remaining spin up electrons gets flipped into the xy plane. This picture of spin reversal is different from that in the Ising-like case.

In conclusion, we present here some examples of new phenomena and insights that can happen in finite temperature spin reversals in ultrathin films. There are many interesting questions that wait to be studied. Finite temperature fluctuation of the domain walls is very important in ultrathin films.

Whereas in three-dimensional situations, domain walls are flat, recent experimental and theoretical results^{6,11} indicate that walls in ultrathin films are not flat. The effect of these on the dynamics of spin reversal is not completely clarified.

There is a similarity between coherent rotation and spinodal decomposition. In both cases the barrier against a continuous change of the order parameter approaches zero. Just as in the case of spinodal decomposition, there may be a scaling relationship for the structure factor of the magnetization in the long time limit near the onset of coherent rotation. A detailed relationship between the two is not clear at the moment and remains to be investigated.

This paper describes a new approach for producing epitaxial Fe overlayers on GaAs(100), which prevents the intermixing of the semiconductor elements in the overlayer. This is accomplished by sulphur passivation of the substrate surfaces in an aqueous ammonium sulphide solution prior to Fe deposition. bcc Fe(100) is observed to grow epitaxially on S/GaAs(100) substrates, with most of the S floating out as an ordered overlayer. No evidence of semiconductor interdiffusion into the Fe overlayer is observed. The Fe overlayers are observed to be ferromagnetic, with easy axes along the [010] directions. A uniaxial in-plane anisotropy is observed, in addition to the expected fourfold anisotropy, which is attributed to the bonding geometry at the interface. The saturation magnetization of these overlayers is found to be close to that of bulk Fe. © 1996 American Institute of Physics. [S0021-8979(96)70908-X]

The growth of magnetic overlayers and multilayers on semiconductors has attracted considerable attention due to the potential for integrating the desired magnetic properties of these systems with computer circuitry. However, in practice, the growth of transition metals on semiconductor substrates is difficult, generally resulting in the intermixing of the semiconductor elements into the overlayer. In the case of the growth of Fe overlayers on GaAs(100), a significant amount of As has been observed to interdiffuse into the overlayer.¹⁻³ This has been shown to result in a significant decrease in the magnetization of these systems.³ This paper describes a new approach for producing epitaxial Fe overlayers on GaAs(100), which prevents the intermixing of the semiconductor elements in the overlayer: the use of sulphur passivated substrates.

It has been recently shown that many semiconductor surfaces (including InP, GaAs, and Ge) can be effectively passivated by treatment in an aqueous ammonium sulphide solution.⁴⁻¹³ These surfaces are thought to be composed of 1 ML of S atoms bridge bonded to the semiconductor surface, essentially continuing the bulk lattice positions.⁴⁻¹³ This configuration results in all of the semiconductor dangling bonds being saturated, producing a chemically passive surface that is extremely resistant against oxidation by air. When such samples are placed into vacuum, they show clean, well-ordered surfaces.

We have investigated the use of S-passivated substrates for the growth of Fe overlayers as a potential means of preventing As interdiffusion into the Fe overlayer. In this investigation Auger electron spectroscopy (AES), low energy electron diffraction (LEED), reflection high energy electron diffraction (RHEED), and static secondary ion mass spectrometry (SSIMS) measurements have been used to examine the structure and check for As interdiffusion in the overlayers deposited at 25 °C. Magnetic characterization of the system

has been accomplished utilizing the magneto-optic Kerr effect (MOKE) and ferromagnetic resonance (FMR) techniques.

Two separate UHV systems were utilized in this investigation. The first system, located at the University of Western Ontario, consists of a diffusion pumped UHV growth/analysis chamber (base pressure $<1 \times 10^{-10}$ Torr) which is connected to a turbo-pumped UHV loadlock chamber (base pressure 2×10^{-10} Torr) equipped with a remote sample transfer arm. The loadlock chamber is also equipped with a MOKE apparatus for the magnetic characterization of the samples. The main growth/analysis chamber is equipped with a liquid nitrogen shrouded Fe evaporation source, a four-grid retarding field analyzer for LEED measurements, a CLAM electron energy analyzer (Fisons Instruments) for AES measurements, and a SSIMS system consisting of a Hiden quadrupole mass spectrometer and a Kimball Physics Cs⁺ ion gun. It is also interfaced to a 2.5 MV Van de Graaff accelerator which was utilized for a Rutherford backscattering calibration of the evaporation rate onto an Al substrate.¹⁴

The second UHV system utilized is a multiple chamber MBE system, consisting of growth, analysis and sample introduction chambers, designed and located at Simon Fraser University. This system is equipped with a double-pass cylindrical mirror analyzer (PHI-10-360, equipped with an OMNI lens) for XPS measurements, a PHI-06-190 RHEED system to monitor the quality of the Fe growth, and a quartz crystal thickness monitor to monitor the Fe coverage.

Additional magnetic characterization of the samples was accomplished by *ex situ* FMR measurements on samples capped with 20 ML of Au. Ferromagnetic resonance (FMR) measurements were carried out using a magnetic microwave spectrometer operating at 24 GHz which has been previously described.¹⁵ The FMR measurements were carried out on 6, 9, 20, 25, and 30 ML thick Fe films.

The S-passivated GaAs(100) samples were prepared *ex situ* by treatment in an aqueous sulphide solution. *n*-type GaAs(100) wafers [aligned to within 0.5° of the (100) direction] from Bertram Laboratories were utilized in these investigations. The GaAs(100) samples were degreased in hot

FIG. 1. The Intensity of the Fe, S, Ga, and As AES transitions as Fe is deposited.

(50–60 °C) methanol and then treated for 20 min. at 65 °C, in an aqueous ammonium sulphide $[(\text{NH}_4)_2\text{S}]$ solution. After this treatment the samples were rinsed with running deionized water and methanol for about 5 min, blown dry with He and inserted into the loadlock chamber. A new sample was utilized for each experiment.

Upon insertion into the vacuum system the samples showed a poor (1×1) LEED pattern and a small amount of C contamination. The samples were annealed to 450 °C prior to Fe deposition to desorb any remaining contaminants and improve the surface order. After this thermal treatment, a sharp (2×1) LEED pattern was observed and the C contamination had been removed. The (2×1) reconstruction is due to the dimerization of the adjacent S rows.

AES and SSIMS measurements were utilized to investigate the presence of As interdiffusion during the growth of the Fe overlayers. Figure 1 shows the variation of the Fe (703 eV), S (152 eV), Ga (1070 eV), and As (1228 eV) AES intensities during Fe deposition. The Fe AES signal initially increases steadily with Fe coverage, leveling off at a coverage of about 7 ML [where 1 ML is the surface atomic density of Fe(100)]. The S AES signal shows an initial decrease, but then levels off and is still at about 70% of its initial intensity at Fe coverage of 20 ML. This persistence of the S signal means that some of the S is floating out on top of the Fe film, as the S electrons would not penetrate a 20 ML film.

Both the Ga and As AES signals decrease in an exponential manner, being undetectable by a coverage of 15 ML. Fitting these data yielded values of 14.3 and 18.9 Å for the Ga and As AES electron mean free paths. These values are in good agreements with the calculated values of 17 and 19 Å,¹⁶ suggesting that the Fe film is uniform and that neither Ga or As is interdiffusing through the overlayer.

SSIMS measurements were utilized to look for As interdiffusion at lower levels, due to the high sensitivity of SIMS for As. SSIMS measurements of the S/GaAs(100) substrate showed strong S and As signals. Fe overlayers of 2, 4, and 6 ML were also analyzed. In all cases, Fe and S signals were clearly visible, with As never being observed. Taking into account the sensitivity of SSIMS for As, this means that the upper limit for the amount of As interdiffusion is 0.01 ML.

The quality of the Fe overlayers was investigated by

FIG. 2. MOKE hysteresis loops for various Fe/S/GaAs(100) overlayers. The applied magnetic field is along the Fe[010] easy axis.

LEED and RHEED measurements. During the initial phase of deposition, the substrate LEED pattern is observed to fade into a rising background, disappearing completely by an Fe coverage of about 1.5 ML. As deposition continues, an overlayer pattern is observed to begin forming at a coverage of about 3 ML, and continues to increase in intensity as deposition continues. The pattern observed was identified as being due to $c(2 \times 2)$ S/Fe(100),¹⁷ indicating that the S floats out in an ordered overlayer on the Fe surface.

RHEED experiments were utilized to provide further information on the substrate and growth morphology. The substrate RHEED pattern showed a laterally well-ordered surface, but also showed that the surface had a strong three-dimensional nature (i.e., it is hilly). As Fe is deposited, the substrate RHEED pattern disappears into a ring of diffuse intensity, indicating that the Fe is polycrystalline. As further Fe is deposited a (2×2) S/Fe(100) RHEED pattern is observed to begin forming at 2.3 ML, with the ring completely disappearing by a coverage of 4.5 ML. The Fe pattern also exhibits the same type of three dimensionality as the substrate, suggesting that the overlayer retains the morphology of the substrate.

The magnetic properties of the Fe/S/GaAs(100) system were investigated by MOKE and FMR measurements. The MOKE measurements showed that for Fe coverages < 4 ML, the samples did not show ferromagnetic behavior. This suggests that the disordering/islanding in the initial interfacial region is sufficient to prevent the development of ferromagnetic ordering. For higher coverages, clear ferromagnetic hysteresis loops are observed, which increase in strength as further material is deposited (see Fig. 2). The rounding observed in these loops likely indicates the presence of some defects in the Fe overlayers, which are pinning the magnetization.

The FMR measurements revealed the presence of uniaxial and fourfold in-plane anisotropies. The fourfold anisotropy had its easy axes along the $\{001\}$ crystallographic

FIG. 3. The effective magnetization as a function of Fe overlayer thickness. The solid line represents the two term fit to the data.

directions, the uniaxial anisotropy had its easy axis along $[0\bar{1}1]$. The in-plane uniaxial anisotropy was strongly dependent on the sample thickness. For the 6 ML thick sample the strength of the uniaxial anisotropy was found to be $2K_u/M_s = 0.1$ kOe, and it decreased to 0.4 kOe in the thickness range of 30 ML. The fourfold anisotropy was increasing with an increasing Fe film thickness: the strength of the fourfold anisotropy $2K_1/M_s$ was close to zero for the 6 ML thick sample, and 0.4 kOe for the 30 ML thick film. The thickness dependence of the in-plane anisotropies was otherwise scattered sufficiently so that no attempt was made to fit the measured results.

The effective magnetization ($4\pi M_{\text{eff}} = 4\pi M_s - H_u$) is shown in Fig. 3 as a function of Fe coverage. The solid line is a fit to the data, obtained using a constant plus $1/d$ term. The constant and $1/d$ terms were found to be 20.7 kG and -86.9 kG/ML, respectively. The constant term is very close to the saturation induction of bulk Fe (21.55 kG), showing that the measured film reached nearly bulk properties at a very low Fe coverage. On the contrary, the films deposited directly on GaAs(001) substrate showed significantly decreased saturation magnetization in the thin-film limit due to a severe interdiffusion of As into the Fe overlayer.³ The undiminished saturation magnetization of films deposited on S-passivated GaAs(001) is in agreement with the previously discussed structural studies, which show no penetration of As into the Fe. The $1/d$ term is most likely associated with the presence of a well-defined perpendicular uniaxial anisotropy. The effective uniaxial surface anisotropy is $K_s = 1.1$ erg/cm² with the easy axis perpendicular to the film surface.

The FMR lines have symmetric peaks, with the linewidths depending on the Fe film thickness. A 25 ML film possessed very narrow FMR linewidths: 60 and 100-Oe for the hard and easy in-plane magnetic axis, respectively. The FMR linewidth was observed to increase with decreasing

film thickness. The 6 ML overlayer exhibited FMR linewidths of 210 and 400 Oe for the hard and easy magnetic axes, respectively. The magnetic properties across the sample were not always homogeneous. The FMR peaks for 9 and 25 ML samples exhibited a large splitting (separated by 2–5 FMR linewidths for the easy and hard axes, respectively) indicating that there was either a problem with the Au capping layer or the samples were inhomogeneous in thickness.

We have shown a new procedure for the growth of Fe overlayers on GaAs(100), the use of S-passivated substrates, that prevents the interdiffusion of the As into the overlayer. Fe(100) has been shown to grow on this substrate, with a layer of ordered S floating out on top of the overlayer. The S acts as a surfactant, holding the Fe on top of the substrate,¹⁷ and not allowing semiconductor interdiffusion into the overlayer. Samples with Fe coverages greater than about 4 ML exhibit ferromagnetic behavior. These samples show the expected fourfold in-plane anisotropy, as well as an additional uniaxial anisotropy. The presence of this uniaxial anisotropy has been previously observed for Fe/GaAs(100)^{3,18} and was attributed to the surface bonding geometry. The effective magnetization can be fit with two terms: a constant term (20.7 kG) and a $1/d$ surface term. The constant term is very close to the saturation induction of bulk Fe (21.55 kG). Thus, the bulk atomic layers in the overlayer behave as expected for bulk Fe. There is no indication of the reduction in magnetization previously attributed to interdiffused As.³

Epitaxial ferromagnetic MnAs thin films grown on Si (001): The effect of substrate annealing

K. Akeura, M. Tanaka,^{a)} T. Nishinaga, and J. De Boeck^{b)}

Department of Electronic Engineering, The University of Tokyo, 7-3-1 Hongo, Bunkyo-ku, Tokyo 113, Japan

We have studied two different types of epitaxial ferromagnetic MnAs thin films on Si (001) substrates grown by molecular beam epitaxy. When the Si substrates were annealed at a relatively high temperature ($\sim 900^\circ\text{C}$) and then MnAs was grown, we obtained epitaxial MnAs films with twofold crystal symmetry (type I). In contrast, when the thermal cleaning of the Si substrate was done at a lower temperature ($\sim 600^\circ\text{C}$), epitaxial MnAs thin films had fourfold crystal symmetry (type II). The growth plane in both types of MnAs thin films was the $(\bar{1}101)$ of the hexagonal MnAs. The type I MnAs films are single domain with strong magnetic anisotropy, whereas the type II MnAs films are double domain with the lack of strong magnetic anisotropy. © 1996 American Institute of Physics. [S0021-8979(96)71008-9]

Epitaxial ferromagnetic metallic thin films on semiconductors are very attractive as a new class of electronic materials,¹ because it is expected that such artificial structures can lead to the integration of magnetism with semiconductor electronics, giving the unprecedented opportunities for new device applications. So far, we have successfully grown epitaxial ferromagnetic MnAs thin films on GaAs (001) substrates by molecular beam epitaxy (MBE) and have found that the starting surface reconstructions and stoichiometry play a critical role in determining epitaxial orientations and magnetic properties.²⁻⁴ Furthermore, very recently, we have successfully grown ferromagnetic MnAs on Si (001) substrates.⁵ The combination of ferromagnetic materials with Si is obviously important for many potential applications, because most of the existing LSI circuitry is based on Si technologies. In the MBE growth of MnAs on Si (001), it was found that supplying As₄ flux first without Mn flux on Si was necessary to obtain MnAs films with good magnetic properties, whereas supplying Mn flux without As flux on Si led to polycrystalline MnAs.

In this paper, we extend this study on MnAs/Si, and show that two types of MnAs thin films with different structural and magnetic properties are epitaxially grown on Si (001), depending on the thermal cleaning temperature of the Si substrates prior to the growth of MnAs.

MBE growth was performed with a conventional III-V MBE machine (ULVAC MBC-508) with a Mn effusion cell. We used Si (001) substrates (*p*-type, boron doped) misoriented 1° towards $[110]$. After being etched with HF solution and dried with N₂ gas, the Si substrates were introduced into the MBE growth chamber. Watching reflection high energy electron diffraction (RHEED), we annealed the substrates at the temperature T_a ($=600$ – 1000°C) for a few minutes to turn the hydrogen-terminated (1×1) Si surface to the clean surface of (2×2) –(001) Si, as shown in Fig. 1(a), which was taken with $[110]$ Si incidence. It is known that the HF etching is very effective to passivate the Si surface, making the

annealing temperature dramatically lower to obtain clean surfaces.⁶ This (2×2) Si surface was first exposed to the As₄ flux, and then the substrate temperature was cooled to 300°C . After this process, Si surface is terminated with 1 monolayer (ML) of As atoms, showing clear (2×2) reconstruction in the RHEED patterns. With the As₄ flux kept on, MnAs epitaxial growth was started by supplying the Mn flux with a growth rate of 0.1 – $0.4\ \mu\text{m/h}$. During the growth the substrate temperature was kept at 300°C and the pressure of As₄ flux was about 1×10^{-5} Torr.

Here, we have found that the annealing temperature T_a

FIG. 1. (a) A RHEED pattern taken from the (2×2) –(001) Si surface after annealing at $T_a=600^\circ\text{C}$ with the incident electron beam along the Si $[\bar{1}10]$, normal to the misorientation direction. Almost the same RHEED pattern is observed after annealing at $T_a>900^\circ\text{C}$. (b), (c), (d), and (e) are RHEED patterns of the type I and type II MnAs thin films with two different electron beam azimuths. (b) Type I, electron beam azimuth//Si $[\bar{1}10]$ \parallel misorientation direction; (c) type I, electron beam azimuth//Si $[\bar{1}10]$ \perp misorientation direction; (d) type II, electron beam azimuth//Si $[\bar{1}10]$ \perp misorientation direction; (e) type II, electron beam azimuth//Si $[\bar{1}10]$ \parallel misorientation direction.

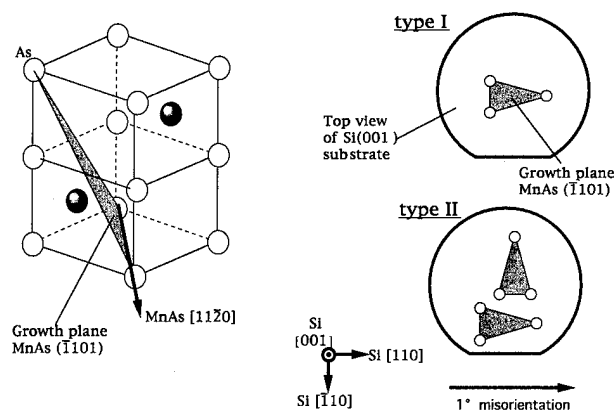

FIG. 2. Crystal structure of the hexagonal MnAs and the $\bar{1}101$ plane are shown on the left-hand side. Top view of the epitaxial relationships of the MnAs/Si(001) system is shown on the right-hand side. The type I MnAs consists of a single domain, in which the axis of MnAs $\bar{1}120$ is along the Si $\bar{1}10$. The type II MnAs has double domains, in which one domain has the MnAs $\bar{1}120$ axis along the Si $\bar{1}10$ and the other domain has the MnAs $\bar{1}120$ axis along the Si $\bar{1}10$, 90° different with respect to the substrate plane.

of the Si substrate prior to the growth of MnAs plays an essential role in determining structural and magnetic anisotropy in the MnAs/Si system. When we annealed the substrate at a relatively high temperature ($T_a \sim 900^\circ\text{C}$) and started the growth of MnAs in the way described previously, we obtained MnAs thin films with the structure of twofold crystal symmetry, which we refer to as type I, as shown by Figs. 1(b) and 1(c) taken from a $1.4\ \mu\text{m}$ thick MnAs thin film. For the type I MnAs thin films, the RHEED pattern with the incident electron beam along the Si $\bar{1}10$ [Fig. 1(b)] is clearly different from that with the incident electron beam along the Si $\bar{1}10$ [Fig. 1(c)]. Here we define the $\bar{1}10$ and $\bar{1}10$ of Si as the direction parallel and normal to the misorientation direction, respectively. The intervals of the streaks in the RHEED patterns of Figs. 1(b) and 1(c) are in good agreement with the lattice constants along the MnAs $\bar{1}102$, $\bar{1}120$ axes, respectively. In contrast, when we annealed the Si substrate at about 600°C , which is high enough to obtain the Si (2×2) reconstruction [Fig. 1(a)], we obtained MnAs thin films with fourfold structural symmetry, which we refer to as type II, as shown in Figs. 1(d) and 1(e) taken from a $0.3\ \mu\text{m}$ thick MnAs thin film. Note here that despite the different annealing temperature, very clear (2×2) –(001) Si surface was obtained for both types, indicating that the starting Si surface has little disorder or contamination. For the type II MnAs, the RHEED pattern of Fig. 1(d) (along the Si $\bar{1}10$ azimuth) is very similar to that of Fig. 1(e) (along the Si $\bar{1}10$ azimuth). X-ray diffraction measurements (θ - 2θ method) were done on both types of MnAs films, and it was found that the growth plane of both types was the $\bar{1}101$ of hexagonal MnAs.

From the RHEED and x-ray results, the epitaxial relationships of the two types of MnAs grown on Si (001) are determined and summarized as shown in Fig. 2. The type I MnAs consists of a single domain in terms of crystallographic orientation, in which the $\bar{1}120$ axis of MnAs is parallel to the $\bar{1}10$ axis of Si. In contrast, the fourfold sym-

metry of the type II MnAs is due to the existence of double domains; in one domain the MnAs $\bar{1}120$ is parallel to the Si $\bar{1}10$ just like the type I, and in the other domain the MnAs $\bar{1}120$ is parallel to the Si $\bar{1}10$, 90° different with respect to the substrate plane.

As shown in Fig. 2, the experimental fact that the uniaxial anisotropy in the type I MnAs films always correlates with the misorientation direction of the Si substrate indicates that atomic steps on the Si surface plays an essential role. We speculate that the difference between the type I and type II MnAs arises from the difference in the initial step structure of the Si misoriented surfaces before growing MnAs. The direction of the Si dimers on the Si (001) substrate and/or the As dimers of the As prelayer seems to determine the alignment of the $\bar{1}120$ axis of MnAs. Although it is difficult to obtain a single-domain Si (2×1) surface on 1° misoriented substrates, it is likely that when we annealed the substrate at high temperature ($T_a \sim 900^\circ\text{C}$), one domain that has Si dimers arranged parallel to the step edge of the Si substrate becomes more or less dominant, compared with the other domain having Si dimers normal to the step edges. Thus, the MnAs thin films grown on this surface tend to have the structure with twofold symmetry (type I). In contrast, when the annealing temperature T_a is relatively low (600°C), the direction of the Si dimers on the substrate surface, either parallel or normal to the step edges, is equally distributed. Therefore, in this case, the MnAs films grown on this surface tend to have double domains, showing the fourfold symmetry in RHEED.

Although in some samples a little polycrystalline character was seen in the RHEED [e.g., Fig. 1(d)], we rule out the possibility that this kind of disorder causes the lack of uniaxial anisotropy in the type II, because the disorder appears in both type I and type II samples. Since the initial (2×2) Si surfaces for both types have no difference in the RHEED properties exhibiting well-ordered reconstruction, this partially disordered character appeared during the epitaxial growth of MnAs, probably due to the the the lack of uniformity of the substrate temperature over the 2-in. wafers. Further refinements of the growth conditions are needed to obtain better quality.

To investigate the magnetic properties of the type I and type II MnAs on Si (001), we have performed magnetization measurements by alternating gradient force magnetometry (AGFM),⁷ on 300 nm thick MnAs thin films of both types. We applied the magnetic field H in various directions and found that the easy axis of the magnetization in both types of MnAs is in-plane. Figures 3(a)–3(d) show the in-plane M - H characteristics at room temperature of type I [(a),(b)] and type II [(c),(d)] MnAs thin films, with H normal [(a),(c)] and parallel [(b),(d)] to the misorientation direction of the Si substrates. A squarelike M - H hysteresis curve was recorded with $H \parallel$ Si $\bar{1}10$, normal to the misorientation direction [Fig. 3(a)], while only a little hysteresis was observed with $H \parallel$ Si $\bar{1}10$, parallel to the misorientation direction [Fig. 3(b)]. Therefore, the type I MnAs has strong magnetic anisotropy in the substrate plane. Considering the epitaxial orientation (see Fig. 2), the easy magnetization axis of the type I MnAs/Si is the MnAs $\bar{1}120$, which is parallel to the Si

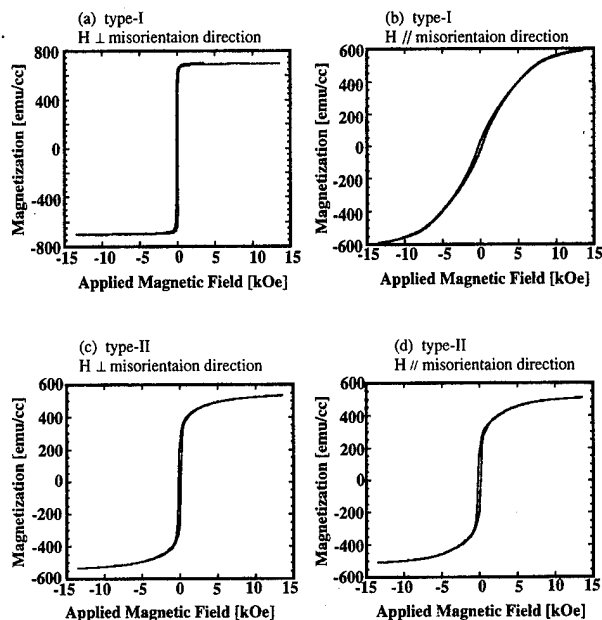

FIG. 3. Room-temperature $M-H$ curves of 300 nm thick type I and type II MnAs films grown on Si. The applied magnetic field H was in-plane. (a) type I, $H//\text{Si } [\bar{1}10] \perp$ misorientation direction; (b) type I, $H//\text{Si } [\bar{1}10]$ misorientation direction; (c) type II, $H//\text{Si } [\bar{1}10] \perp$ misorientation direction; (d) type II, $H//\text{Si } [\bar{1}10]$ misorientation direction.

$[\bar{1}10]$. When H is along the easy axis, the saturation magnetization (M_s), remnant magnetization (M_r), and coercive field (H_c) of this 300 nm thick type I MnAs is 690 emu/cc, 625 emu/cc, and 94 Oe, respectively. In contrast, the $M-H$ curves of the type II MnAs on Si showed some hysteresis when H was applied both along the Si $[\bar{1}10]$ and along the Si $[\bar{1}10]$ as shown in Figs. 3(c) and 3(d). The M_r and H_c values of Figs. 3(c) and 3(d) are 217 emu/cc and 124 Oe, and 162 emu/cc and 148 Oe, respectively, similar to each other. This indicates that the type II MnAs films consist of two crystal-

lographic domains; in one domain the MnAs $[\bar{1}120]$ axis (the easy magnetization axis) is along the Si $[\bar{1}10]$, and in other domain the MnAs $[\bar{1}120]$ is along the Si $[\bar{1}10]$. The existence (type I) and the lack (type II) of strong magnetic anisotropy in type I and type II are consistent with the structural analysis.

In conclusion, we have grown two types of ferromagnetic MnAs thin films on Si(001) by MBE. The two types of MnAs have different crystal symmetry, caused by the different annealing temperature of the misoriented Si substrates. In-plane magnetic anisotropy was characterized for both types of MnAs on Si, consistent with the structure analysis. This result indicates the importance of the starting surface in controlling the structure and magnetic properties in the epitaxial MnAs/Si system.

The authors wish to thank Y. Matsunaga for useful discussions on the MBE growth on Si substrates. Thanks are also due to the cooperation of M. Ueki at the initial stage of this work. Thickness dependence of effective magnetic anisotropy

Ching-Ray Chang

Department of Physics, National Taiwan University, Taipei, Taiwan, Republic of China

Taking into account the occurrence probability of holes and imperfections we derive the nonlinear thickness dependence of the product Kt in very thin films. We predict both the usual $1/t$ and the recently observed $1/t^2$ dependence of the effective magnetic anisotropy K from the stochastic model. Agreement between theory and published experimental data is very good. © 1996 American Institute of Physics. [S0021-8979(96)71108-5]

The surface properties of ultrathin films have recently attracted considerable interest. One of the most appealing new features, both from the point of view of fundamental physics¹⁻³ and of potential applications to information storage,^{4,5} is magnetic anisotropy induced by symmetry breakdown at the film surfaces. Magnetic anisotropy in bulk ferromagnets differs considerably from that in thin films,⁶ it is often written^{7,8} as $E_A = KV \sin^2 \theta$ where θ is an angle between the magnetization direction and the normal to the film, V is the film volume, and K is effective anisotropy energy density. Its deviation from the bulk value usually varies with the film thickness t as $1/t$ and is therefore attributed to the two film surfaces:

$$K = K_V + \frac{2K_S}{t}, \quad (1)$$

where K_V is the magnetic volume anisotropy which includes shape and crystalline contributions and K_S is the magnetic surface anisotropy (MSA). The influence of the surfaces (or interfaces) can be large enough to change the preferential orientation of magnetization in the film from in-plane to perpendicular.⁹

The physical origin of MSA has been studied qualitatively before and several possible mechanisms were proposed. A series of first-principles calculations on Co-based multilayers shows the order of the magnetic anisotropy is 1 meV/Co and it is simply related to the spin-orbit interaction.^{3,10-12} Despite these advances in our understanding there remain some features of MSA in multilayers which could not until now be explained even qualitatively, to wit, most data exhibit a kink in the t dependence of the product Kt and a peculiar $1/t^2$ dependence of the effective magnetic anisotropy K has also been reported.^{8,13} However, most of the first-principles calculations are based more on the situation of the perfect interface and neglect the roughness and imperfection of the interface. Indeed, roughness reduces the magnitude of K_S , especially for the sputtered samples¹⁴ and the growth imperfection will result in a reduction of K_S from its intrinsic value of an ideal plane. When the interface is very rough, the effective areas of the interface reduces and the measured K_S also decreases.¹⁵

Some experimental results suggest that islandlike structures form on ultrathin films.⁴ Magnetostatic¹⁶ and strain calculations¹⁷ also indicate that film imperfections can result in nonlinear t dependence of the product Kt . However, the influence of the imperfection film was largely ignored in most theoretical studies which concentrated for simplicity on

continuous films; to understand it we must first consider the actual film growth mechanism during which the imperfections arise. This is a difficult problem involving complicated many-body effects, our goal here is to develop a simple independent column growth model covering the most essential features. Here we do not intend to simulate the real, complicated epitaxial system, we only want to demonstrate the imperfection film existing even in our simple model, and its possible dependence on the film thickness. The basic idea is that atoms to be deposited on the substrate are highly energetic and form, in effect, an ideal gas of Brownian particles. After adsorption they undergo redistribution, but on a cold, rapidly quenching substrate the adsorbed atoms are not free to move around and can, therefore, be approximately treated as randomly deposited. Within this simple model of rapidly quenched Brownian particles we develop a stochastic description of the surface area covered during film deposition and then employ a heuristic argument to take into account the effects of redistribution.

The film growth is modeled as a process of random deposition of M atoms over N sites so that the average thickness of the film is $t = M/N$ layers. An exact combination expression for the occupation probability of a chose site is, of course, available but a simple geometric argument illustrated in Fig. 1 shall suffice for sufficiently large $N < M$. The probability of at least one of the N sites being empty is then $P_0^{(1)} \sim 1/t$ while the effective area ratio P_f^1 , the probability of

FIG. 1. There are $N=4$ sites over which $M \gg 4$ atoms are distributed, and the film thickness $t = M/N$. The occupation numbers of each of the four sites are J_1, J_2, J_3 , and $J_4 = M - J_1 - J_2 - J_3$, respectively, with the subsidiary condition $J_1 + J_2 + J_3 \leq M$. The number of all possible configurations is approximately equal to the simplex volume and the number of configurations with at least one site empty approximately equal to its surface area. The surface to volume ratio is then $N'/M \cdot [N' + \sqrt{N'}] \sim 1/t$, where $N' = N - 1$.

FIG. 2. The probabilities $P_f^1(t)$, $P_f^2(t)$, and $P_f^3(t)$ that a film formed by random deposition of $5000t$ Brownian particles over 5000 sites does not have at least a single site hole, at least a 2-site contiguous hole and at least a 3-site contiguous hole respectively. Note that contiguous holes are extremely rare. The plots show results of numerical simulations.

the film being free of holes, equals $1 - P_0^{(1)}$. To verify this expression we used a Monte Carlo simulation in which five hundred samples of $M = 5000t$ atoms were randomly distributed over 5000 sites and averaged. The simulation results (Fig. 2) confirm the $1/t$ dependence of $P_f^{(1)}(t)$ for large enough t .

Adsorbed atoms have a certain probability of undergoing redistribution by means of surface diffusion. It is a reasonable assumption that interatomic attractive forces shall preferentially remove small holes which were initially randomly distributed in the film.¹⁸ The probability of at least two neighboring deposition sites being empty is $P_0^{(2)} = O(1/t^2)$ and $P_f^{(2)} = 1 - P_0^{(2)}$ therefore represents the occupation probability after redistribution which, by assumption, removed single-site holes. We simulated the probability $P_f^{(2)}$ of the film not having a small (at least two sites) contiguous hole. Figure 2 shows that $P_f^{(2)}$ deviates from unity only for very thin films and, as predicted, $P_0^{(2)} \sim 1/t^2$ for sufficiently large t . By extension, on a very warm substrate only larger, n -site holes survive redistribution with probability $P_0^{(n)}(t) = O(1/t^n)$ (see Fig. 2 for $n=3$).

After the film growth and redistribution processes, there are still certain chances, e.g., $P_0(t)$, that the film can have holes, and the effective area ratio of the interface is not unity, i.e., $P_f(t)$. On the average, the film still can have a well-defined surface anisotropy K_S , however, its magnitude should be proportionally decreasing because of holes. Usually, thinner film results in the larger holes and the films may even break up into patches when it is very thin (Fig. 2). However, some thick films also tend to form columnar structures because of the geometrical self-shadowing effects¹⁵ which are not included in our independent column growth model.

According to Eq. (1) the anisotropy energy within the

FIG. 3. Comparison between experimental data (Ref. 4) and the proposed Eq. (2).

volume $V = St$ of a film of surface area S is $E_A = (K_V V + 2K_S S) \sin^2 \theta$ but our previous considerations show that the surface area S should be modified by the effective area ratio $P_f(t)$ that there exists a film surface at all:

$$Kt = K_V t + 2K_S P_f(t). \quad (2)$$

This modification of Eq. (1) is our key result. An explicit expression for the probability $P_f(t)$ is likely to be very complicated, because of the redistribution effect. All $1/t^n$ terms should appear at $P_f(t)$ simultaneously and we propose here the heuristic, single parameter formula $P_f(t) = \exp(-R/t) = 1 - R/t + o(R/t)$. Exponential functional form is chosen to exhibit all $1/t^n$ terms and R is an adjusting parameter. For $K_V < 0$ a kink (maximum) appears in the plot of the product Kt while for large enough t the usual formula (1) is recovered. In Fig. 3 we show the plot of Kt_{Co} for the experimental data of Ref. 4 together with the best fit according to Eq. (2). Using the reported volume anisotropy energy,^{4,5} $K_V = -0.72$ MJ/m³, the best fit gives $K_S = 0.55$ mJ/m² and $R = 2.5$ Å. The fitted magnetic surface anisotropy is the same as reported value of K_S for Co/Pt multilayers.¹⁹ It is interesting to point out that R is about one atomic layer of Co and is very close to the reported surface roughness of Co film⁷ (≈ 2 Å). This result suggests that the parameter R of our heuristic formula is related to surface roughness, but we cannot provide any rigorous proof.

As mentioned above, a $1/t^2$ thickness dependence of the effective anisotropy constant K has been reported for ultra-thin films with perpendicular magnetization, such as fcc Fe/Cu¹³ and Au/Co/Au(111) multilayers.⁸ Within our model we expect such films to have holes with probability $P_0^{(1)} \sim 1/t$ so that $K = O(1/t^2)$ by Eq. (2). Our heuristic formula was also successfully used in interfacial curling model explaining the enhanced coercivity of coated particles.²⁰ We cannot substantiate our conjecture that redistribution effects lead to higher order thickness dependence since there exist, to the

best of our knowledge, no experimental data relating the effective anisotropy K to surface diffusion rate.

Although the independent column growth model is quite simple, however, it covers the most fundamental features of the film growth process and reveals the facts of the imperfection of the interface. Any more realistic simulations should still be manifested as the similar form of the Eq. (2). We wish to emphasize that the proposed modification of surface properties, i.e., their intrinsically stochastic nature, does not effect only MSA but every other surface related quantity.

Uniaxial and planar magnetic anisotropy of thin transition-metal films (abstract)

R. Lorenz and J. Hafner

*Institut für Theoretische Physik and Center for Computational Materials Science, Technische Universität
Wien, A 1040 Wien, Austria*

We present a novel approach to the calculation of the spin structures and magnetic anisotropies in crystals and thin films. Our technique is based on self-consistent real-space recursion calculations on a tight-binding linear muffin-tin orbital (TB LMTO) Hubbard Hamiltonian including spin-orbit coupling and allowing for arbitrary orientations of the local spin-quantization axes. It allows one to scan the magnetic energy continuously as a function of the orientation of the magnetic moment and thus to avoid the computational problems that plague other techniques. Applications are presented for bulk iron and for thin Fe overlayers on Cu (111) and Cu (100) substrates. For monolayer coverage, we predict a perpendicular direction of the magnetic moment for Fe/Cu(100) an in-plane orientation of the spins for Fe/Cu(111), with anisotropies of the order of 1–2 meV. For Fe/Cu(100) we present a detailed investigation of the variation of the spin structures and of the change from perpendicular to in-plane anisotropy with increasing thickness of the Fe films. © 1996 American Institute of Physics. Structural and magnetic properties of face-centered-cubic Fe films grown on Co(100)

Ernesto J. Escorcia-Aparicio, R. K. Kawakami, and Z. Q. Qiu

Department of Physics, University of California at Berkeley, Berkeley, and Materials Science Division, Lawrence Berkeley National Laboratory, Berkeley, California 94720

A rich variety of magnetic and structural properties have been found in fcc Fe films grown on Cu(100). In order to better comprehend the relation between the magnetic and structural properties of fcc Fe, we investigated fcc Fe films grown by molecular beam epitaxy on fcc Co(100). Structural characterization by low-energy electron diffraction and reflection high-energy electron diffraction indicate that the structural properties of fcc Fe films grown on Co(100) at room temperature are very similar to those of fcc Fe on Cu(100), exhibiting three distinct regions (fct, fcc, and bcc), with characteristic reconstructions at the boundaries. Magnetic measurements with *in situ* surface magneto-optic Kerr effect (SMOKE) reveal in-plane magnetization at room temperature for the three regions. Regions I and III are ferromagnetic, while region II has a small Kerr signal which is constant throughout the region. Cusps in the coercivity of the SMOKE loops are found to correspond to transitions between the three regions. Oxygen absorption experiments performed at room temperature revealed no change in the magnetization of region II, suggesting that the live layers responsible for the magnetic signal in this region are not at the surface. © 1996 American Institute of Physics. [S0021-8979(96)71208-1]

Films of fcc Fe grown on Cu(100) at room temperature exhibit three regions with distinct structural and magnetic properties. Low-energy electron diffraction (LEED) and reflection high-energy electron diffraction (RHEED) measurements yield a fct phase for Fe thickness (d_{Fe}) < 5 ML, a fcc phase for d_{Fe} ~ 5–11 ML, and a bcc phase for d_{Fe} > 11 ML.^{1–6} Characteristic LEED reconstruction patterns associated with each phase have also been identified.^{1–6} It has been shown that the fct phase is ferromagnetic^{2,3,7–9} and the fcc phase is antiferromagnetic with a live magnetic surface layer.^{8,9} Both phases have out-of-plane magnetization with the ordering temperature below room temperature.^{2,3,7–9} The bcc phase is bulklike ferromagnetic with in-plane magnetization.^{2,3,7–9} Cusps in the coercivity of the magnetic hysteresis loops coincide with the transitions between the structural phases.^{8,9} These results have led to the conclusion that there is a strong correlation between the structural and magnetic properties of Fe/Cu(100).^{1–4,7} In light of this, the natural avenue to pursue is to ascertain which of the magnetic properties of the films are more susceptible to modification through structural changes by studying which magnetic properties are more closely tied to the structure.

In this paper, we shall report on experiments performed on ultrathin Fe films grown by molecular beam epitaxy (MBE) on fcc Co(100). The Co(100) substrate was obtained by growing a few monolayers (ML) of Co on a Cu(100) single crystal. Since Co has magnetic properties of its own, we wished to create a substrate that would structurally be similar to Cu(100), with added magnetic properties, in the hope that we would be able to separate which effects were due to structure and which ones to magnetic effects.

All samples were epitaxially grown in an ultrahigh vacuum (UHV) chamber with a base pressure of $\sim 2 \times 10^{-10}$ Torr. The UHV system is equipped with effusion cells, thickness monitor, RHEED, LEED, Auger electron spectroscopy (AES), Ar⁺ ion sputtering, and an *in situ* surface magneto-optic Kerr effect (SMOKE) setup with both longitudinal and polar configurations. A sample manipulator provides a tem-

perature range of 120–900 K and permits the use of all the above techniques at different stages of a single chamber.

The single-crystal Cu(100) substrate was mechanically polished down to 0.25 μm diamond paste and finished with vibration polishing using 0.05 μm Al₂O₃ powder. The substrate was then cleaned in UHV with cycles of Ar⁺ ion sputtering at 2–5 keV and annealing at 650 °C. AES was used to ensure the cleanliness of the surface. For the growth of Fe on a dirty substrate, we observed as many as 40 RHEED oscillations accompanied by a 2×2 reconstruction in the LEED pattern, consistent with the report of Li *et al.*⁹

For all of the specimens reported here, a 6 ML fcc Co(100) film was epitaxially grown at room temperature onto the Cu(100) to form the substrate. The pressure during growth remained below 6×10^{-9} Torr. The Fe film was grown on top of the Co(100) either with a uniform thickness to study the LEED reconstruction and RHEED oscillations, or with a wedge shape to facilitate the thickness dependence study.

The structural properties of the room-temperature growth Fe/Co(100) system were investigated by RHEED and LEED. RHEED intensity was monitored during film growth and is shown in Fig. 1. Three regions can be identified: a region of erratic oscillations, followed by a region with fairly periodic and constant oscillations which gives way to a region where the oscillations disappear and the RHEED intensity is greatly decreased. The RHEED patterns for regions I and II are consistent with a fcc-like crystal structure, while the pattern for region III is consistent with bcc islandlike growth. Studies performed on the Fe/Cu(100) system^{2,3,7–9} have yielded similar RHEED oscillation patterns. Other studies performed on the Fe/Cu system have shown that there, region I has a pseudo-fct crystal structure, while regions II and III are fcc and bcc, respectively.^{1–6} The great similarity between the RHEED patterns and oscillations of the Fe/Cu and Fe/Co systems is consistent with the assertion that regions I, II, and III have, respectively, fct, fcc, and bcc crystal structures in both systems.

FIG. 1. Typical RHEED intensity variations during Fe deposition on fcc Co(100). Samples were grown at room temperature with a growth pressure $<6 \times 10^{-9}$ Torr. Different oscillatory behaviors identify three distinct regions, which are indicated. RHEED and LEED patterns show no difference between the Fe/Co(100) and Fe/Cu(100) systems.

A sample in which layers of Fe were uniformly grown on top of Co(100) was used to study reconstruction between regions I and II, taking a LEED picture after each successive growth. In particular, LEED patterns for pure Co and 2, 3.5, and 6 ML of Fe on Co were carefully studied. The pure Co and 2 ML of Fe (region I), showed a sharp 1×1 structure. The LEED pattern for 3.5 ML of Fe (transition between regions I and II), showed a 4×1 or 5×1 reconstruction. Finally, the pattern for 6 ML Fe coverage (region II) showed a 1×1 or a weak 2×1 reconstruction. Wedge samples of Fe on Co(100) yielded similar results. Experiments performed on the Fe/Cu(100) system yield a 1×1 reconstruction for region I, $4-5 \times 1$ reconstruction for the transition region between regions I and II and a 2×1 reconstruction for region II. The similar structural behaviors of the Fe/Cu and Fe/Co systems suggest that the structural properties of the fcc Fe are purely determined by the underlayer crystal structure, and are independent of the magnetic properties of the substrate.

Magnetic measurements were performed using the *in situ* SMOKE technique. Each of the three structural regions was observed to have a distinct magnetic behavior. In contrast to the room-temperature growth Fe/Cu(100) system, where the magnetization is out-of-plane in the first two regions with an ordering temperature below room temperature,^{2,3,7-9} the room-temperature growth Fe/Co(100) system exhibits in-plane magnetization throughout the thickness range with an ordering temperature well above room temperature. Since both Co and Cu produce the same crystal structure for the Fe overlayer, we attribute the different magnetic behavior of the Fe/Co systems to the magnetic nature of the Co substrate.

We first studied the effect of the Co layer thickness on the magnetization of the Fe by growing identical Fe wedges on a different thickness of Co (2–20 ML). The results of two of these experiments, for 6 and 10 ML of Co are shown in Fig. 2. The two curves have a similar shape, but are offset from each other due to contribution from the Co. If the Co Kerr signal is subtracted from both, as in Fig. 3, both curves coincide precisely. Therefore, 6 ML of Co is enough for all

FIG. 2. Longitudinal Kerr signals of Fe wedges grown on different thicknesses of fcc Co(100) at room temperature. A study of the effect of Co thickness on the Fe/Co(100) system was performed by growing identical Fe wedges on different thicknesses of fcc Co(100). Two typical curves for 6 and 10 ML of Co are shown. Only in-plane magnetization was found in these samples throughout the whole thickness range.

the features of the Fe/Co system to be present. The choice of 6 ML as the Co thickness for most of our experiments was purely arbitrary.

Region I, which goes from 0 to 10 Å (6 ML) of Fe, is ferromagnetic with the Kerr intensity proportional to d_{Fe} . The Kerr signal drops to a small and constant level in region II, which goes from 10–20 Å (6–11 ML) of Fe. In region III, the Kerr signal increases and again acquires a ferromagnetic character. Since all three regions exhibit in-plane magnetization, we are able to compare directly the magnitudes of the Kerr signals in these three regions. It is interesting to note that the magneto-optic responses for regions I and III fall roughly on the same line, suggesting that the Fe film retains the magnitude of the magnetic moment as its structure

FIG. 3. (a) The same Kerr signals as in Fig. 2 with the Co backgrounds subtracted. The curves are identical for both Co thicknesses. Measurements were taken at room temperature. Note that the magneto-optic response in regions I and III falls roughly on the same line. (b) Cusps in the coercivity of the SMOKE loops were observed to correspond to the transition between regions.

changes from fcc to bcc. We attribute the different magnetic behavior between the Fe/Co and Fe/Cu systems to the ferromagnetic nature of the Co layer. We believe that it is the direct polarization of the Fe by the Co moment at the interface that causes the in-plane magnetization and the enhanced ordering temperature in the Fe/Co system as compared to the Fe/Cu system. To support our idea about direct coupling between Fe and Co, we investigated the shape of the magnetic hysteresis loop of the Fe/Co film. If the Fe overlayer were not coupled to the Co underlayer, a hysteresis loop for a Fe/Co film would have a step at the fields corresponding to the coercivities of Fe and Co. What we observe, however, is a single square loop with the coercivity shifted from that of Co to a new value as d_{Fe} increases. The coercivity of the Fe/Co system versus d_{Fe} is shown in Fig. 3. Just as in the Fe/Cu system, as reported by Li *et al.*,⁸ we observed cusps in the coercivity at the transitions between the three structural regions.

Region II seems to be the most interesting of the regions in this system. The fact that the Kerr signal is constant throughout the whole region, seems to imply that there are only a few layers that are magnetically live. A similar live layer was also found in the Fe/Cu system below room temperature and seems to come from the surface layer of the Fe film. Since the live layer in our Fe/Co system was observed at room temperature and there exists a direct magnetic coupling between Fe and Co, we speculate that the live layer in the Fe/Co system originates from the interface of Fe and Co instead of the surface layer of the Fe. To determine this, an Fe wedge grown on 6 ML Co was prepared and SMOKE measurements were performed just as described previously. A small amount of oxygen was leaked into the chamber so that it would react with the surface of our sample (a few minutes at 10^{-7} Torr). In principle, the oxygen would react with a few surface layers of our sample and if the magnetic live layers of the fcc region were located at the surface, we would see a change in the Kerr signal. A complete SMOKE scan across the wedge was performed after the oxygen absorption. The results of the SMOKE scans both before and after oxygen absorption are shown in Fig. 4. The most salient result is that the Kerr signal in region II remains the same, implying that the magnetic live layers for this region are not located at the surface. It can also be observed that region I and the transition to region II are shifted to regions of greater d_{Fe} , while the transition to region III seems virtually unaffected. The shift can be explained by realizing that if the oxygen removes magnetic layers from the surface, the thickness of Fe is effectively diminished. Also, since the fct and fcc phases are metastable, it is not inconceivable that the introduction of an oxide phase on the surface would cause a shift in the transition region, especially for regions so thin that surface effects are easily felt in the rest of the film. The fact that the transition to region III does not shift can be attributed to the fact that taking off layers in the surface cannot prevent the shift to the more stable bcc phase.

In conclusion, we have been able to grow fcc Fe on fcc Co(100). Structurally, the Fe/Co(100) system has been shown to be very similar to Fe/Cu(100). The basic magnetic features for both systems have been found to be very similar.

FIG. 4. Oxygen absorption experiment performed to ascertain the origin of the magnetic live layers in region II. SMOKE scans before and after oxygen absorption are shown. The shift in region I is evidence that the oxygen reacted with the surface. The magnitude of the Kerr signal in region II remains unchanged after absorption, implying that the magnetic live layers in this region are not at the surface.

Both initially have a ferromagnetic region for low coverage with a fct crystal structure. A second region is fcc and has only a few magnetic live layers. The third region is bcc and is again ferromagnetic. We believe that the difference in the plane of polarization and the ordering temperature for both systems is due to the Co polarizing the Fe moments at the interface. For both cases, cusps in the coercivity of SMOKE loops are observed. Li *et al.*^{8,9} have reported that the fcc region for the Fe/Cu(100) system is antiferromagnetic with a ferromagnetic surface layer and that the antiferromagnetic coupling oscillation period is 2.6 ML. This noninteger period would seem to indicate the presence of spin-wave effects. Our experiments with oxygen absorption show that there is no live layer at the surface for the Fe/Co(100) system. We have seen evidence of the polarization of the Fe moments at the interface which would seem to indicate that the magnetic live layers are at the interface. Further work should concentrate on trying to determine whether there are antiferromagnetic coupling oscillations at lower temperatures. Also, the use of different growth conditions for this system should help further delineate the differences between the Fe/Cu(100) and the Fe/Co(100) systems.

Epitaxial MnAs films on GaAs(001) in the thickness range 20–200 nm were studied. Using ordinary and extraordinary Hall effect data to determine the field required for perpendicular saturation and saturation magnetizations reported elsewhere, we determined the shape anisotropy constant in the basal plane of the hexagonal structure to be $3.7(0.6) \times 10^5$ erg/cm³ and the surface anisotropy constant to be $-1.3(0.4)$ erg/cm². The negative sign indicates thin enough films will be perpendicularly magnetized. By magnetic force microscopy of a 100 nm film we found stripe domains with 180° Bloch walls, thereby avoiding the hard *c* axis. The widths of the domains and the walls are 4.0(0.3) μ m and 95(6) nm, respectively. In magnetoresistance, we observed behavior similar to other ferromagnets, namely peaks centered around the positive and negative coercive fields, and at fields beyond the coercive field a linear dependence on magnetic field. The electrical resistance showed rapid increase with temperature beginning about 5° below the Curie temperature (40 °C) caused by the change in crystal structure from hexagonal to orthorhombic. The resistivities are, respectively, 300(24) and 375(30) $\mu\Omega$ cm. Comparison with bulk values indicates the large lower temperature value is partly due to the presence of some orthorhombic phase observed in x-ray studies. © 1996 American Institute of Physics. [S0021-8979(96)71308-8]

INTRODUCTION

Recently we reported initial results on the molecular beam epitaxy (MBE) growth of MnAs films on GaAs substrates,¹ and showed that they have excellent magnetic properties with almost square hysteresis loops, relatively high remanent magnetization ($M_r=301\text{--}567$ emu/cm³) and relatively low coercive field ($H_c=65\text{--}926$ Oe).²

MnAs/GaAs is a new, epitaxial, ferromagnetic system with potentially useful magnetic properties. As such, it is worthwhile to measure a variety of properties to obtain an overall view. Here, we report galvanomagnetic properties (magnetoresistance, Hall effect, electrical resistance) obtained using a four-point probe method and magnetic domain structure using magnetic force microscopy (MFM). Additional structural and magnetization studies will be reported elsewhere.

EXPERIMENT

MnAs films with thicknesses of 20, 50, 100, and 200 nm grown on GaAs(001) substrates were used in this work. The easy axis is in the film plane in the $[-1, -1, 2, 0]$ direction. The *c* axis is a hard axis also in the film plane in type A films and 39° out of the plane in type B. The films are hexagonal, but type A contains some paramagnetic orthorhombic phase near the substrate interface.² The magnetoresistance and Hall effect of these films were measured at room temperature using an ac four-point probe technique.³ The frequency of the ac current was varied in the range from 400 to 1000 Hz while its amplitude was kept constant at 1 mA. Electrical resistance was measured at temperatures from 25 to 60 °C.

The domain structure of a 100 nm type B film was investigated by means of MFM using a commercial atomic force microscope.⁴ The noncontact mode of operation was used to measure the forces between a magnetic tip and the magnetostatic stray field of the sample. Typically the tip was rastered 50–100 nm above the surface.

RESULTS AND DISCUSSION

The longitudinal magnetoresistance (MR) of a 100 nm MnAs film is displayed in Fig. 1(a). Here the field is in the easy direction parallel to the current in the plane of the sample. In Fig. 1(a) the linear part of the curve beyond the coercive field H_c (VSM value ± 324 Oe) is due to *s-d* electron scattering as explained by Mott.⁵ The peaks in Fig. 1(a) occur at the transition region observed in the vicinity of H_c in the VSM hysteresis loop and are centered at about H_c . The peaks are attributed to electron scattering from the domain walls.⁶ Figure 1(b) shows the thickness dependence of the longitudinal magnetoresistance ratio, defined as resistance at zero field minus resistance at maximum field (± 1400 Oe) divided by resistance at zero field.

The extraordinary Hall effect (EHE) voltage or resistance is linearly proportional to the component of the magnetization perpendicular to the plane of the film. Figure 2(a) shows the field dependence of the Hall resistance R_{xy} of a 20 nm film. Below the saturation field H_s the linear slope is related to the EHE and above H_s it is related to the ordinary Hall effect, which is much smaller. The data are fit to two straight lines whose intersection is taken to be H_s , which in this case is ~ 5500 Oe. The magnitude of H_s is given by

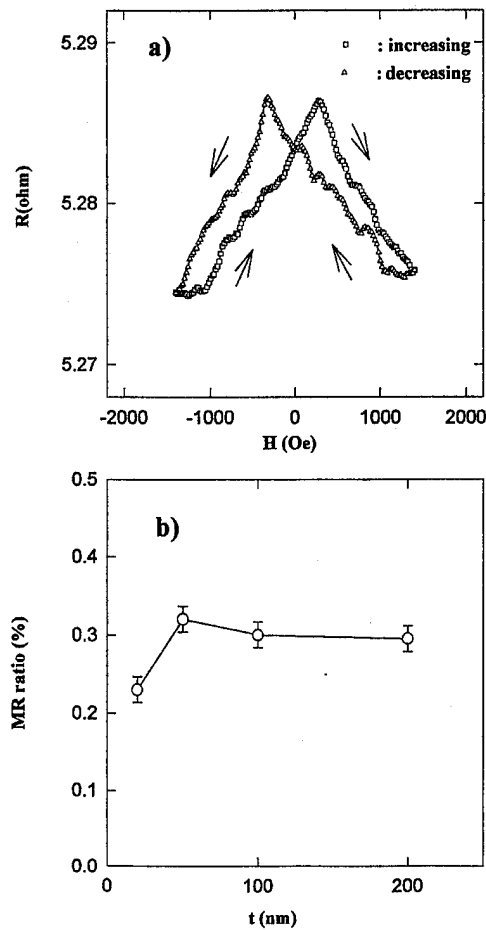

FIG. 1. (a) Resistance variation with applied field in the longitudinal geometry, 100 nm film. (b) Magnetoresistance ratio as a function of thickness from 20–200 nm.

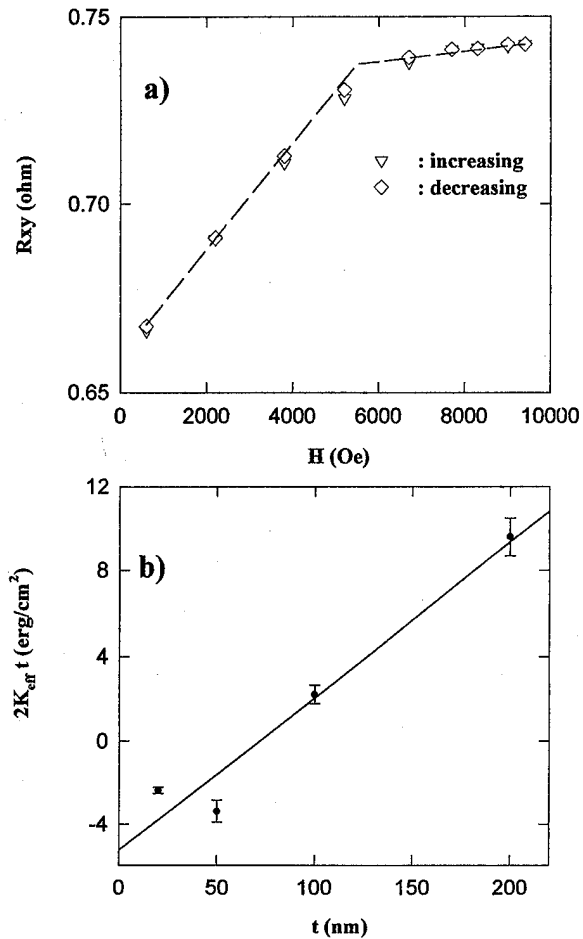

FIG. 2. (a) Hall resistance vs applied perpendicular field, 200 nm film. (b) Effective anisotropy constant times thickness as a function of thickness from 20–200 nm.

$H_s = 4\pi M_s + 2K_{eff}/M_s$, where K_{eff} is the effective anisotropy constant. K_{eff} can be written as $K_v + 2K_s/t$. Here, K_v is the shape anisotropy constant for the crystal plane perpendicular to the c axis, i.e., the basal plane of the MnAs structure, which in type A is also perpendicular to the film plane and t the thickness of the film. K_s is the surface anisotropy constant. Using the VSM values of M_s and the Hall effect values of H_s , we find the effective anisotropy constant shown in Fig. 2(b) versus film thickness. The straight line is a least-squares fit yielding $K_v = 3.7(0.6) \times 10^5$ erg/cm³. The c -axis anisotropy constant is about ten times larger. The fit gives $K_s = -1.3(0.4)$ erg/cm², the negative sign causing K_{eff} to become negative below about 75 nm, favoring perpendicular magnetization, which is opposed by the demagnetization energy. A thin enough film will show perpendicular magnetization.

Figure 3 shows the electrical resistance of a 200 nm film over the temperature range of 25–60 °C. Beginning about 5° below the Curie temperature (40 °C) the electrical resistance shows a rapid increase with temperature, which is caused by the change in crystal structure from hexagonal to orthorhombic that occurs in this temperature region, as observed by us in unpublished x-ray studies. See also Ref. 7 for x-ray results on bulk MnAs. We have measured the resistivity of the 200 nm film using the van der Pauw method,⁸ which gives a

directional average. Its value at 25 °C, 300(24) $\mu\Omega$ cm, is ~ 1.5 times greater than that of the bulk hexagonal phase⁹ (~ 180 $\mu\Omega$ cm) along the c direction. A number of factors, such as strains, the presence of some orthorhombic phase,

FIG. 3. Resistance variation with temperature, 200 nm film.

FIG. 4. MFM images of 100 nm film. x and y dimensions 20 μm . (a) z distance is proportional to force derivative. Arrow shows easy axis $[-1 -120]$. (b) Brightness is proportional to force derivative; (c) line scan along path shown in (b).

and scattering at the interfaces, could account for the higher film resistivity. At 60 $^{\circ}\text{C}$ we find 375(30) $\mu\Omega\text{ cm}$ to be compared with the bulk orthorhombic value of $\sim 360\text{ }\mu\Omega\text{ cm}$.⁹ The closer agreement is expected since the film at 60 $^{\circ}\text{C}$ is single phase. Resistivity measurements in the bulk are difficult and poorly reproducible due to thermal fracturing of the samples, which is absent in our films.

Figure 4 shows MFM images of a 100 nm type B film in its demagnetized state. This film has an easy axis in-plane and hard c -axis tilted up 39 $^{\circ}$. In Fig. 4(a) the z direction (out of the film plane) shows not film height, but the vertical gradient of magnetic force. In Fig. 4(b) the force gradient is shown only by color variations. The broad bands are the domains, and as indicated in the figures their magnetizations lie along the easy axis in alternate directions. The vertical spikes are due to noise. In Fig. 4(b) it can be seen that alternate domain walls show a bright or dark line. The bright line indicates direction of magnetization perpendicularly up from the film, and the dark line shows the reverse. Thus the domain walls are 180 $^{\circ}$ Bloch type. We believe this is the first MFM image of in-plane magnetized stripe domains. This shape is expected since the domains will avoid the very hard c axis. We find the average domain width is 4.0(0.3) μm and

the domain wall width is 95(6) nm as given by the lines at the domain walls.

To better understand the brightness variation from one domain to another in Fig. 4(b) we have done the line scan shown in Fig. 4(c) along a path across the domains as shown in Fig. 4(b). This result agrees with the line scan calculated by Mamin *et al.*¹⁰ corresponding to a tip having equal longitudinal and transverse components of its magnetization.

To achieve higher GMR ratios in spin valves, $\text{Co}_{90}\text{Fe}_{10}$ films were used as the free and the pinned layer. A single layer of CoFe 100 Å and a multilayer of $\text{CoFe } 18 \text{ Å}/(\text{Cu } 8 \text{ Å}/\text{CoFe } 18 \text{ Å})_5$ were used as the free layer. Although the single layer CoFe showed large coercivities of 58 Oe along the easy axis and 40 Oe along the hard axis, the multilayer $\text{CoFe } 18 \text{ Å}/(\text{Cu } 8 \text{ Å}/\text{CoFe } 18 \text{ Å})_5$ showed smaller coercivities of 10 Oe along the easy axis and 1.5 Oe along the hard axis on a 100 Å thick Ta underlayer. The anisotropy field of the multilayer was 20 Oe. The film structures of the free layer were evaluated and it was found that the multilayer had higher oriented (111) texture than the single layer. The reason why the multilayer had higher oriented (111) texture was that the Cu layers between CoFe layers helped to have highly oriented (111) texture. To reduce the anisotropy field, the film was annealed in a magnetic field perpendicular to the initial easy axis at several temperatures. As the result, the anisotropy field was reduced to 3 Oe and the coercivity was 4 Oe after annealing at 140 °C. The GMR ratio of the spin valve of Ta 100 Å/CoFe 18 Å/(Cu 8 Å/CoFe 18 Å)₄/Cu 24 Å/CoFe 30 Å/FeMn 150 Å/Ta 50 Å was 7% after the annealing. © 1996 American Institute of Physics. I. INTRODUCTION

Spin valves which consist of a free and a pinned magnetic layer with a nonmagnetic spacer layer¹ are prime candidates for read heads in future magnetic recording systems. Spin valves with NiFe in the magnetic layers show 3%–4% GMR ratio. In order to achieve higher performance in spin valves, higher GMR ratio is preferable. It is reported that utilizing Co as the pinned and the free-magnetic layer gives higher GMR ratio than utilizing NiFe because the Co layer gives larger spin dependent scattering at the interface.^{1,2} However, it is difficult to use Co film as the free layer because it does not show soft magnetic properties. The coercivity is more than 30 Oe.³ If Co or Co-based films gives soft magnetic properties, higher performances can be achieved in spin valves. In this study, we have tried to achieve soft magnetic properties in Co-based alloy films by making the films into multilayers and we have used this multilayer as the free layer of our spin valve. We also explored how annealing in a field affects the magnetic properties of the Co-based free layer and the pinned layer.

II. EXPERIMENTAL PROCEDURE

Films were sputter deposited on glass (Corning No. 7059) in a uniform dc field.⁴ $\text{Co}_{90}\text{Fe}_{10}$ alloy target was used for the deposition of the magnetic layer because the content gave zero magnetostriction. The magnetic properties of single layer CoFe and multilayer CoFe with Cu interlayers were investigated. Spin valve films were prepared and GMR versus field curves were evaluated. The standard structure of the spin valve films (except for the free layer) was of Ta(100 Å)/free layer/Cu(24 Å)/CoFe(30 Å)/FeMn(150 Å)/Ta(50 Å).

The microstructures of the CoFe films were evaluated by x-ray diffractometry using $\text{Cu K}\alpha$ x-ray and atomic force microscope (AFM). Annealing and cooling in a magnetic field was also performed. The magnetic field during the annealing and the cooling was 100 Oe and was perpendicular to the initial easy axis and the initial pinned direction. Samples were kept for 1 h at the annealing temperature.

III. EXPERIMENTAL RESULTS

A. GMR and magnetic properties

Figures 1(a) and 1(b) show the GMR versus field curves

FIG. 1. (a) and (b) are GMR vs field curves of spin valves with single layer CoFe for the free and the pinned magnetic layer. The film structure is of Ta 100 Å/CoFe t_f Å/Cu 24 Å/CoFe t_p Å/FeMn 150 Å/Ta 50 Å. (c) is a GMR vs field curve of a spin valve with a multilayer of $\text{CoFe } 18 \text{ Å}/(\text{Cu } 8 \text{ Å}/\text{CoFe } 18 \text{ Å})_4$ for the free magnetic layer. The film structure is of Ta 100 Å/free layer/Cu 24 Å/CoFe 30 Å/FeMn 150 Å/Ta 50 Å.

FIG. 2. The hysteresis loops of (a) a 100 Å thick CoFe single layer and (b) a multilayer of CoFe 18 Å/(Cu 8 Å/CoFe 18 Å)₅ on a 100 Å thick Ta underlayer.

of spin valves using single-layer CoFe for both the free and the pinned layer. The applied field was parallel to the pinned direction. When the thickness of both the CoFe free and pinned layers is 100 Å (a), there appears a large hysteresis about 130 Oe at the magnetic reversal of the free layer. The hysteresis of the pinned layer is also much larger than 100 Oe. The hysteresis of the free layer is so large that the GMR property is not suitable as a magnetic field sensor. When the thickness of both the CoFe free and pinned layers is 30 Å (b), the GMR curve shows two peaks and one of the peaks is much smaller than the other, which is not suitable as a magnetic field sensor. The hysteresis curve ($B-H$ curve) of this sample was also evaluated and it was found that this peak imbalance occurred because the magnetic reversals of the free and the pinned layer occurred at almost the same field when the applied field increased from a negative value to a positive value. Since the reason for the overlap of the magnetic reversals was caused by the small pinning field of 40 Oe, a larger pinning field was needed.

In order to improve the magnetic properties of the CoFe free layers, first, the thickness dependence of the coercivity of CoFe was investigated. As a result, the coercivity decreases from 58 to 12 Oe on decreasing the thickness from 100 to 30 Å, which means a thinner free layer is effective in achieving low coercivity. However, a 30 Å thin free layer showed only a small pinning field and a poor GMR versus field curve as shown in Fig. 1. Therefore we tried to make the free layer into a multilayer using Cu as the interlayers. Figure 2 shows the hysteresis loops of a 100 Å thick CoFe single layer and a multilayer of CoFe 18 Å/(Cu 8 Å/CoFe 18 Å)₅, on a 100 Å thick Ta underlayer. In the figure, hysteresis loops along the easy and the hard axis are shown. Both of the coercivities along the easy and the hard axis decrease drastically, from 58 to 8 Oe along the easy axis and from 40 to 1.5 Oe along the hard axis by the multilayering. The dispersion angles α_{50} were also evaluated, which was 35° in the single layer and 2° in the multilayer. The anisotropy field in the multilayer was about 20 Oe, which is relatively large comparing NiFe film.

Utilizing the multilayer as the free layer, spin valve films were deposited. The structure was: Ta 100 Å/CoFe 18 Å/(Cu 8 Å/CoFe 18 Å)₄/Cu 24 Å/CoFe 30 Å/FeMn 150 Å/Ta 50 Å. The GMR versus field curve is shown in Fig. 1(c). There are two discrete loops coming from the magnetic reversal of the

free layer and the pinned layer. Comparing the GMR curve of the spin valve which have a 30 Å thick single layer CoFe for the free layer, the pinning field increased up to 140 Oe. The coercivity of the free layer is about 10 Oe, which is much smaller than that of the 100 Å thick CoFe spin valve of Fig. 1(a). The reason we chose this CoFe thickness (18 Å) for the free layer was that CoFe thickness smaller than 20 Å gave smallest coercivity in the free layer, but the thickness smaller than 15 Å gave smaller pinning field. As for the Cu thickness (8 Å), larger Cu thickness gave worse squareness in the magnetic reversal of the free layer.

B. Structural study of the free layer

To investigate the microstructure of the free layer, we made a 630 Å thick single layer film of CoFe and a multilayer film of CoFe 18 Å/(Cu 8 Å/CoFe 18 Å)₃₄ on a 100 Å thick Ta underlayer. In these films, the total CoFe thicknesses were the same. Although these films were thicker than the actual free layer of spin valves, they showed similar magnetic properties to the actual thick free layer, which meant that the multilayer film of CoFe 18 Å/(Cu 8 Å/CoFe 18 Å)₃₄ showed much smaller coercivity (10 Oe) and much smaller dispersion α_{50} (4°) than those of the single layer CoFe film (the coercivity was 35 Oe and the dispersion α_{50} was 12°). In the x-ray spectra ($\theta-2\theta$ scan) of these films, there appeared fcc (111) peak in both of the films. The peak height of the multilayer film was four times of the height of the single layer. The half-height width of the multilayer was smaller than that of the single layer and the estimated grain sizes from the half-height widths were 180 Å for the multilayer and 120 Å for the single layer.

In the rocking curves of the fcc (111) peaks of these films, the half-height width of the multilayer was 8.2° and was much smaller than that of the single layer (12.1°), which meant that (111) planes in the multilayer were much more oriented than those in the single layer. To find the reason why the multilayer had a more highly oriented (111) texture, we investigated the crystal growth of Cu on a CoFe layer. 630 Å thick Cu layers were deposited on a film of Ta 100 Å/CoFe 18 Å and on a film of Ta 100 Å. The rocking curves of the Cu(111) peak of these samples were measured. The half-height width of the Cu layer on a 18 Å thick CoFe layer was much smaller than that of the Cu layer on Ta. From these results, a Cu layer on a CoFe layer tends to have a much more highly oriented (111) texture than a CoFe layer and as a result, the multilayer of CoFe and Cu had a more highly oriented texture than the CoFe single layer.

AFM images of the multilayer CoFe 18 Å/(Cu 8 Å/CoFe 18 Å)₃₄ on Ta underlayer and the single layer CoFe 630 Å were observed. The grain size of the multilayer from the image was about 400 Å, which was larger than that of the single layer (≈ 300 Å). The grain sizes obtained from the AFM image were almost double those obtained from the half-height widths of x-ray spectra, but these results of AFM images and x-ray spectra were consistent qualitatively. However, it was not fully understood why the multilayer showed much smaller coercivity than the single layer. The magnetic properties might be related to the texturing of the film.

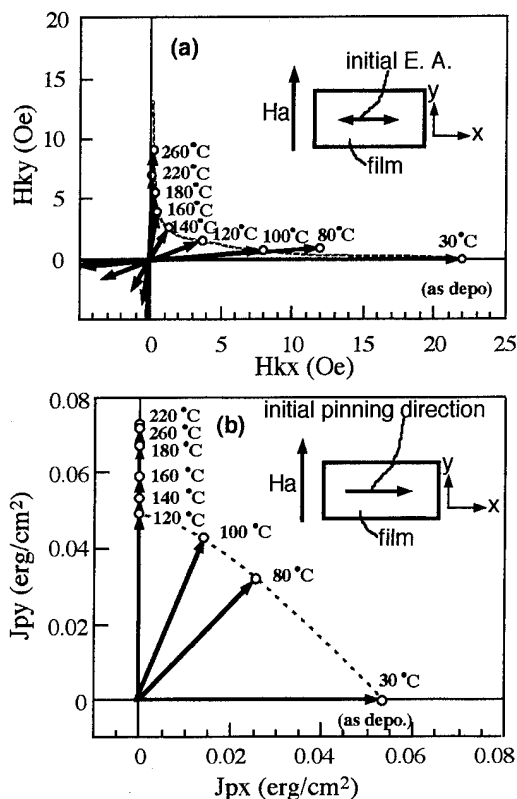

FIG. 3. Vector figures of (a) the anisotropy field of the free layer and (b) the coupling constant between the pinned layer and the antiferromagnetic layer after annealing for 1 h at several temperatures. A field of 100 Oe was applied perpendicular to the initial easy axis and the initial pinning direction during annealing and cooling.

C. Annealing effect

As shown in Fig. 2, the as-deposited anisotropy field H_k of the CoFe multilayer was still relatively large. In order to reduce the anisotropy field of the free layer, we investigated how annealing affects the anisotropy field in the free layer and the pinning field in the pinned layer. A magnetic field of 100 Oe was applied perpendicular to the initial easy axis and the initial pinning direction during the annealing and the cooling down.

Figure 3(a) shows how the anisotropy field changes with annealing. Increasing the annealing temperature, the direction of the anisotropy field rotates from the initial easy axis to a direction perpendicular to the initial easy axis. The magnitude of the anisotropy decreases from 22 to 3 Oe with increasing annealing temperature to 140 °C and it increases with increasing the temperature from 140 °C. Figure 3(b) shows the pinning direction and the coupling constant be-

FIG. 4. GMR vs field curves of a CoFe spin valve and a NiFe spin valve. The samples are of (a) Ta 100 Å/CoFe 18 Å/(Cu 8 Å/CoFe 18 Å)₄/Cu 24 Å/CoFe 30 Å/FeMn 150 Å/Ta 50 Å after annealing at 140 °C and (b) Ta 100 Å/NiFe 100 Å/Cu 24 Å/NiFe 75 Å/FeMn 150 Å/Ta 50 Å.

tween the pinned layer and the antiferromagnetic layer after annealing at several temperatures. The direction of the arrows shows the pinning direction and the length of the arrows shows the coupling constant between the pinned layer and the antiferromagnetic layer. The pinning direction rotates from the initial direction toward the direction of the applied field during annealing. The pinning direction rotates by 50° away from the initial direction when the annealing temperature is 80 °C. It becomes parallel to the direction of the applied field during annealing when the temperature is higher than 120 °C. The coupling constant decreases with increasing the temperature from RT to 120 °C and it increases with increasing temperature from 120 to 220 °C.

Figure 4 shows the GMR versus field curve after annealing at 140 °C, which gives the smallest anisotropy field in the free layer. In the same figure, a curve of a NiFe lower case spin valve is also shown for comparison.⁴ The coercivity of the CoFe spin valve is 4 Oe, which is of comparable value of that of the NiFe spin valve. The slope at the magnetic reversal of the free layer is almost the same as that of the NiFe lower case spin valve.

Micromagnetics of uneven ultrathin film trilayers

A. S. Arrott

Simon Fraser University, Burnaby, British Columbia V5A 1S6 Canada

For ferromagnetic sandwiches where two iron layers are separated by a middle layer, the strength of the coupling sharply varies with each change in the thickness of the middle layer. If the interfaces were sharp on the atomic scale, one could observe this directly, or else one can use micromagnetics to take into account the actual morphology of less than ideal interfaces as shown by Slonczewski. As an approximation the average magnetization in each layer is found from a phenomenological energy that contains the competition between bilinear and biquadratic exchange constants that depend on surface roughness. More detailed micromagnetic calculations using relaxation methods to treat spatial variations of the magnetization in each layer are given for Fe-Cr-Fe sandwiches. The approximate calculations give jumps in the magnetization at critical fields, but these are smeared out in the more detailed calculations. For the special case of equivalent layers, the phenomenological expression for the energy can be used to obtain analytic expressions for the field dependence of the magnetization. © 1996 American Institute of Physics. [S0021-8979(96)71608-7]

Two ferromagnetic ultrathin films separated by a nonferromagnetic ultrathin film is called a trilayer sandwich. The ferromagnetic layers can be treated as magnetic units that couple to each other in a way that depends on the properties of the middle layer and its two interfaces. Theory and experiment show that the variation of the thickness by one atomic layer d_0 is sufficient to make large changes in that coupling, sometimes reversing the sign with each additional atomic layer.¹ If interfaces were perfect one could determine $U_0(nd_0, \theta_1, \theta_2)$, the dependence of the coupling energy per unit area for perfectly flat layers, and how it changes with the thickness of the middle layer, $d=nd_0$, and the angles of the moments in the ferromagnetic layers. But interfaces are not perfect. The measured quantities depend on averaged interactions which depend on averaged angles, averaged layer thicknesses $\langle n \rangle$, and the range of layer thicknesses Δn . If the films are such that at most, three thicknesses of the interlayer are present it is possible to deconvolute the interlayer exchange from experiments on less than perfect samples.²

The foundations for this subject have been well set by Slonczewski.³ To a first approximation

$$U_{\text{eff}}(\langle n \rangle, \Delta n, \theta_1, \theta_2) = J_1(\langle n \rangle, \Delta n) \cos(\theta_1 - \theta_2) - J_2(\langle n \rangle, \Delta n) \sin^2(\theta_1 - \theta_2) \quad (1)$$

where J_1 is called the bilinear exchange and J_2 is called the biquadratic exchange. These depend on the interlayer exchange and the surface roughness. To obtain the magnetic response to a field H applied in the plane of the sandwich, one must add the anisotropy energy and the Zeeman energy. The total energy per unit area is

$$U = U_{\text{eff}} - \sum_{i=1}^2 H \sigma_{si} \cos \theta_i + K_i \sin^2 \theta_i \cos^2 \theta_i, \quad (2)$$

where σ_{si} is the magnetic moment and K_i is the fourfold, in-plane, magnetic anisotropy energy, both per unit area, for the two ferromagnetic layers, $i=1$ and 2 . Both σ_s and K depend on the thickness of the given layer. In a proper experiment σ_s and K would be known for each of the layers from previous experiments on individual layers. The layers

should be thin enough that the exchange coupling produces a high degree of alignment of moment directions through the thickness. Equation (1) describes the situation where the interfaces are atomically flat except for islands that are one atom rises or one atom depressions called mesas or antimesas. The model is applicable when the mean separation of the mesas is comparable to or smaller than the exchange length.

In analyzing experimental results one can use Eq. (1) with its two parameters J_1 and J_2 , or one can go back to the calculus of variations that underlies the model to determine the spatially varying magnetization in each of the two layers where the parameters are the desired $J(n)$ for perfect layers. The latter is computationally intensive with a relaxation calculation needed for each point on a curve of the field dependence of the magnetization; an example is given below for a sandwich of 20 atomic layers of Fe coupled to 40 atomic layers of Fe through Cr. It is much less work to compute the magnetization from Eqs. (1) and (2). In the simplest case where the two ferromagnetic layers are indistinguishable, there are analytic solutions for the magnetization which are given below. This case is explored in detail in that it provides a road map for exploration of more realistic models.

A straightforward approach, using Eqs. (1) and (2), is to calculate the energy for all pairs of angles for a series of fields, following a local minimum from one field to the next. Local minima become inflection points at critical fields. For each local minimum there can be upper and/or lower critical fields. A particular example for equivalent layers is shown in Fig. 1, where the lower energy contours are shown for four fields $H\sigma_s/(2J_1)=0.35, 0.5, 0.7$, and 0.85 for $K=J_1$ and $J_2=0.2J_1$. The darker regions in Fig. 1 have higher energy. The corresponding magnetizations are discussed below.

For this special case of equivalent layers, analytical results follow by introducing the normal coordinates, $\theta=(\theta_1+\theta_2)/2$ and $\Delta=(\theta_1-\theta_2)/2$. For $\theta=0$, the moments in the two layers rotate in opposite senses. For $\Delta=0$, the moments are locked together. For the ranges of field for which $\theta=0$ is an equilibrium solution, the energy is given by

$$U = 2[(-2J_2+K)\cos^4\Delta + (J_1-2J_2+K)\cos^2\Delta - \sigma_s H \cos \Delta] - J_1. \quad (3)$$

FIG. 1. For the case of equivalent layers, contours of equal energy for $-\pi/2 < \theta_1 < 0$ and $0 < \theta_2 < \pi/2$ for Eqs. (1) and (2) with $K=J_1 > 0$ and $J_2=0.2J_1$. In (a), (b), (c), and (d), $H\sigma_s/(2J_1)=0.35, 0.52, 0.70$, and 0.85 , respectively. The local minimum that starts in (a) near $\theta_1=-\pi/2, \theta_2=\pi/2$ moves along the diagonal toward the fully aligned state at $\theta_1=\theta_2=0$ without falling into the deep minima on either side; see (c). If K is slightly decreased, the path is through one of the side minima.

The relation between $m_x \equiv \cos \Delta \cos \bar{\theta} = \cos \Delta$, the magnetization relative to saturation, and the field is given by

$$\frac{H\sigma_s}{2J_1} = \left[\frac{K-2J_2}{J_1} (1-2m_x^2) + 1 \right] m_x. \quad (4)$$

From Eqs. (3) and (4), it can be seen that the biquadratic exchange is equivalent to a fourfold anisotropy when $\bar{\theta}=0$. The field dependence of m_x is shown in Fig. 2 for a range of effective anisotropy $K_{\text{eff}} \equiv (K-2J_2)$. For $0.2J_1 > K_{\text{eff}} > -J_1$, the m_x curves are completely reversible. For $K_{\text{eff}} > 0.2J_1$, m_x jumps to saturation with a decrease in energy as seen in the

FIG. 2. Field dependence of (a) the relative magnetization, m , and (b) the energy, $U-U_s$, for symmetric configurations with $\theta_1=-\theta_2$. U_s is the energy of the saturated state in the same field. The normalized effective anisotropy, $K_{\text{eff}}/J_1 \equiv (K-2J_2)/J_1$ varies as noted from curve to curve. In (a) the thin lines correspond to unstable equilibria and the dotted lines to jumps at instability points. It can be seen in (b) that, when $K_{\text{eff}}/J_1 > 0.2$, the energy is greater than at saturation for a range of fields below the instability field. For $H=\sqrt{2}J_1/\sigma_s$, $m=1/\sqrt{2}$ independent of K_{eff} .

lower portion of Fig. 2, which shows $U-U_s$, where U_s is the energy for the saturated state at the particular field. For $K_{\text{eff}} < -J_1$, m_x jumps on reversal. In real materials there are many nucleation sites with the result that the magnetization often finds a route to the lowest energy state. Thus, there are reversals in very small reverse fields and jumps to saturation at less than the critical fields. For $K_{\text{eff}} > 0.2J_1$, the jumps to saturation would then occur close to the fields for which $U-U_s$ goes through zero (see Fig. 2).

In addition to the saturated states and the states with counter-rotating magnetizations, there are states where σ_{x1} and σ_{x2} differ. In the ranges of J_2 and H for which $\bar{\theta} \neq 0$, the relation between H and $m_x \equiv \cos \Delta \cos \bar{\theta}$ is given parametrically as a function of $\bar{\theta}$. As the function contains two square roots, there are four combinations of the signs in front of the radicals. There are ranges of $\bar{\theta}$ for which there are no solutions of the equation that relates Δ and $\bar{\theta}$; these ranges depend on J_1/K and J_2/K . In terms of $x \equiv \cos \Delta \equiv \cos[(\theta_1-\theta_2)/2]$ and $y \equiv \cos \bar{\theta} \equiv \cos[(\theta_1+\theta_2)/2]$, the energy is

$$U = -J_1(1-2x^2) - J_2[1-(1-2x^2)^2] - 2\sigma_s Hxy + 2K[x^2(1-x^2) - 8x^2y^2(1-x^2)(1-y^2) + y^2(1-y^2)]. \quad (5)$$

Minimizing with respect to Δ and $\bar{\theta}$, produces analytical expressions for the dependence of H and x on y :

$$\frac{H\sigma_s}{2K} = \frac{y}{x} (-2y^2+1)(8x^4-8x^2+1), \quad (6)$$

$$x^2 = \frac{Y_a \pm \sqrt{Y_a^2 - 8KY_b y^2(2y^2-1)}}{4Y_b}, \quad (7)$$

$$Y_a = -J_1 + 2J_2 + K(8y^4-1),$$

$$Y_b = 2J_2 + K(4y^2-1). \quad (8)$$

The relative magnetization is given by $m_x = xy$.

One can only begin to catalog the range of behaviors encompassed by these equations for $\bar{\theta} \neq 0$ along with the saturated and symmetric solutions, $\Delta=0$ and/or $\bar{\theta}=0$. Here, it helps to be specific. The case investigated is that of Fig. 1 where $J_1=K$ and $J_2=0.2J_1$, for which $(K-2J_2)=0.6J_1$. The dependence of m_x and U on H is shown in Fig. 3. In low fields the lowest energy states have $\bar{\theta}=0$. The magnetization is reversible on path I(*Opqr*). The state with $\bar{\theta}=0$ becomes unstable at *r*, where the saturated state and the state on path II(*abcd*) with $\bar{\theta} \neq 0$ have almost the same energy. If one looks with sufficient precision, the state maintains $\bar{\theta}=0$ as m_x jumps to saturation. In Fig. 1, one can see the small local minimum sneaking along the divide between the two deep minima. With a slight change in the parameters, or with a slight rotation of the field direction, the configuration jumps to path II with $\bar{\theta} \neq 0$, even though this reduces m_x slightly. Path II is stable between point *a*, where on decreasing fields it jumps to path I, and point *d*, where on increasing fields it jumps to the saturated state.

FIG. 3. Field dependence of (a) the relative magnetization, m , and (b) the energy U , for the case, $K=J_1>0$ and $J_2=0.2J_1$, illustrated in Fig. 1.

At the field corresponding to A in Fig. 3, the energy is the same on both paths. If there is nucleation, this is where the jump might occur. One could speculate on what might happen on nucleation from a high field. Is the jump from saturation to path I or to path II? Such questions are answered in more realistic models where the magnetizations in the two sublattices adjust suitably at critical points. In terms of Eq. (1), J_2 is field dependent near the critical fields.

An example of a more realistic calculation is given for a sandwich of Fe–Cr–Fe with one atom high variations in the thickness of the middle layer from place to place on a scale comparable to the exchange length. Now the exchange interactions $A_i[(dM_{ix}/dx)^2 + (dM_{iy}/dx)^2 + (dM_{iz}/dx)^2 + (dM_{jx}/dx)^2]$ for $i=1,2$ come into the calculation explicitly. [They are already included in the derivation of Eq. (1).] The exchange between the layers is described by a local interaction directly across the middle layer $U(x,y) = J(x,y)(M_{1x}M_{2x} + M_{1y}M_{2y})$. In the middle layer there are islands (mesas) of greater thickness for which $J(x,y) = -J$ (ferromagnetic) imbedded in a matrix (plains) of lower thickness where the $J(x,y) = J$ (antiferromagnetic).

FIG. 4. The variation of the magnetization along a line from the center of a mesa where the coupling is ferromagnetic to the middle of the region of antiferromagnetic coupling between the mesas, a distance of 50 nm which is about 3 exchange lengths. Note, that in low fields the antiferromagnetic coupling penetrates well into the ferromagnetic mesa. The mesas are illustrated in the upper-right-hand side corner. The derivatives of the magnetization vanish on the boundaries of the shaded triangle used for calculation.

FIG. 5. The field dependence of the magnetization for the simulation of a sandwich of 20 atomic layers of Fe separated by 11 atomic layers of Cr from 40 atomic layers of Fe. The mean spacing of the mesas is 70 nm as determined by electron diffraction. The area fraction covered by the mesas is varied from curve to curve as indicated. The model assumes that the interlayer exchange J oscillates in sign with each additional atomic layer in the interface. The interlayer exchange $J=J_1=1.5$ erg/cm² is chosen to match a measured upper critical field H_2 . As the area of the mesas of ferromagnetic coupling, $J=-J_1$, is increased, the lower transition approaches the measured lower critical field H_1 . The upper curve is calculated from Eq. (2) using the known anisotropies and magnetizations for 20 and 40 layers of Fe and choosing $J_1=1.0$ erg/cm² and $J_2=0.25$ erg/cm². It does not give the curvatures found in the relaxation model and in the experimental results.

In low fields, the two layers will be coupled close to parallel in the mesas and close to antiparallel in the plains. In between, $M_{ix}(x,y)$ and $M_{iy}(x,y)$ change with position. It is assumed for simplicity that the islands are periodic in x and y ; see upper-right-hand side corner of Fig. 4. The calculation was originally meant to simulate a real experiment⁴ which had 20 atomic layers of Fe separated by 11 atomic layers of Cr from an Fe whisker substrate. The choice of 40 atom layers for the base layer in the model was to emulate the bulk by replacing it by an effective strongly coupled layer. In the experiment there were two fields, H_1 and H_2 , where the magnetization showed changes of state (see Fig. 5). The anisotropy, magnetization, and exchange constants in each layer are known. The only adjustable parameters in the calculation were J and the area of coverage by mesas of ferromagnetic coupling. The mesa separation was ~ 70 nm.

A relaxation method⁵ is used to solve for the magnetization patterns at a series of fields. The magnetization along a line joining second neighbor mesas is shown in Fig. 4. The magnetization of the thicker layer remains close to the field direction for all fields. The magnetization of the thinner layer remains close to antiparallel until a critical field ~ 1.5 kG, where they turn to $\sim 90^\circ$ with respect to the field. This is discontinuous at low coverage and continuous for higher coverage. The dotted lines in Fig. 5 indicate the fields where two different configurations have the same energy.

The suppression of discontinuous jumps is a major difference between the more realistic relaxation calculation and the model with biquadratic exchange independent of field.

Magnetization of two-dimensional XY magnets with symmetry breaking fields: Relevance to ultrathin magnetic films (abstract)

J. Rothman and P. C. W. Holdsworth

Laboratoire de Physique Théorique ENSLAPP, URA 14-26 du CNRS, Ecole Normale Supérieure de Lyon, 69364 Lyon, France

S. T. Bramwell

Department of Chemistry, University College London, London WC1H 0AJ, United Kingdom

The magnetization of ultrathin films shows a power law dependence on temperature with an exponent β that depends on the spin anisotropy. Experimentally it is found that films with easy-axis anisotropy show $\beta=1/8$, characteristic of the two-dimensional Ising model, while those with dominant easy-plane anisotropy show $\beta=0.23$. We recently discussed the finite size magnetization of the XY model and showed that this system has universal behavior which leads to the exponent $\beta=0.23$. A number of authors have therefore interpreted their results in terms of the finite size two-dimensional XY model. The success of these explanations implies that the four- and sixfold anisotropy fields present in real films are irrelevant in determining the critical behavior of the magnetization. In the sixfold case this observation agrees with theoretical expectations, while in the fourfold case the situation is unclear, as the renormalization group analysis of José *et al.* shows the fourfold field to be a marginally relevant variable which gives rise to nonuniversal exponents. This theoretical result, however, pertains to the thermodynamic limit and is not necessarily relevant to real finite systems. We investigate the effect of symmetry breaking fields on the magnetic behavior of idealized finite size XY models by means of Monte Carlo simulation. We find that the fourfold field is indeed irrelevant for the system sizes of interest, and may only become relevant for system sizes beyond the physical domain. We also confirm that the sixfold field is both qualitatively and quantitatively irrelevant, and notice a number of novel features connected with the behavior of finite size models which cannot be observed in the thermodynamic limit. © 1996 American Institute of Physics. Characterization of iron-oxide films grown on Cu(001) and Ag(001) (abstract)

L. Scipioni and B. Sinkovic

Department of Physics, New York University, New York, New York 10003

Ultrathin films of different phases of iron oxide have been grown in UHV on Cu(001) and Ag(001) substrates by reactive evaporation and their structural and magnetic properties measured. By varying the oxygen partial pressure during growth, the oxide stoichiometry was varied from Fe/O=2/3 (fully oxidized) to Fe/O=3.5, as measured by AES and XPS, spanning: FeO, α -Fe₂O₃, Fe₃O₄, and oxide+metal films. LEED patterns and STM images reveal that all of the films grow with a (111) surface orientation with two domains rotated 90° from each other. Films with Fe/O>1 exhibit a 16×1 superstructure induced by the presence of Fe-metal atoms localized at oxide/substrate interface, as found by XPD measurements. Their net magnetization is perpendicular to the film plane, while the films without an interfacial Fe-metal layer exhibit in-plane magnetization. The fully oxidized films (α -Fe₂O₃) exhibit an antiferromagnetic behavior. Temperature dependences of MOKE signal from thin Fe₃O₄ films indicate enhancement of Verwey transition. © 1996 American Institute of Physics. [S0021-8979(96)67808-X]

Thickness dependence of magneto-optical properties in face-centered-cubic Co/Cu(001) ultrathin films

Magneto-optical Kerr spectra of ultrathin Co films grown on Cu(001) surfaces have been measured *in situ*. The growth mode and the crystal structure have been investigated by reflection high-energy electron diffraction observation. A 20-Å-thick fcc Co grown on Cu(001) had a lateral lattice constant of 3.59 ± 0.01 Å, which was about 1.4% expanded compared with that of the bulk fcc Co. There was a remarkable difference above 4 eV in $\omega\sigma_{yz}$ spectra between 20- and 1000-Å-thick films. $\omega\sigma_{yz}$ spectra for 20-Å-thick Co film showed a resonance-type structure at around 5 eV. It is considered that the structure is caused by the lower energy shift of the 1→6 interband transitions due to the narrowing of the 3d bands. © 1996 American Institute of Physics. [S0021-8979(96)71708-6]

The magnetic properties of ultrathin film and multilayer systems with Co have received much attention in recent years due to the fundamental interest in these properties and their potential applications. These multilayers exhibit novel and unique properties in their magneto-optical properties.^{1,2} Recently, Weller *et al.* have presented the polar Kerr spectra of thick fcc Co film.³ There is a clear difference in polar Kerr spectra between the fcc and hcp phases. It is considered that the unique magneto-optical properties in the multilayers are relevant to the crystal structure of the magnetic layers. In addition, a strong dependence of the magnetic properties of fcc Co films on their structure and growth conditions has been found.^{4,5} However, there are few studies aimed at exploring the effect of the influence of the structure on the magneto-optical properties of fcc Co films. In this article, we report the results of the *in situ* observation of magneto-optical Kerr effect spectra during the epitaxial growth of fcc Co on the Cu(001) surface.

The samples were prepared by means of electron beam heating. The base pressure of the deposition chamber was below 5×10^{-11} Torr. A polished MgO single crystal was used as a substrate. After a heat treatment of the substrate at 830 °C, a Ag buffer layer, 1000 Å thick, was deposited to alleviate the lattice mismatch between Cu and MgO and then a 2000-Å-thick Cu seed layer was deposited. The Co layers were grown on this seed layer at room temperature. The thickness of the film was measured by a calibrated quartz thickness monitor. The growth rate of Co was 2 Å/min. The growth mode and crystal structure were monitored during the deposition by a reflection high-energy electron diffraction (RHEED) apparatus with a digital camera system.

After the deposition, the sample was transferred from the deposition chamber to another connected measurement chamber and ellipsometric measurements were performed *in situ*. The angle of incident was set at 55.7°. The complex Kerr effect $\phi_k + i\eta_k$ was measured by the Faraday-cell modulation method. The complex optical constant $n + ik$ was measured by the rotating analyzer method. All experiments were carried out in the photon energy range of 1.7–5.1 eV at room temperature in a remanent state in order to reduce the Faraday effect in vacuum windows. The measurement was repeated after each Co layer deposition in an angstrom step

up to 20 Å. The entire measurement time required for each sample was less than 1 h in a background pressure of 1×10^{-9} Torr.

RHEED patterns observed during the growth of 1000 Å Co essentially maintained the same fourfold symmetry as that of the Cu(001) surface. A conventional x-ray diffraction scan for 1000-Å-thick Co showed only a fcc(002) peak with an interlayer spacing of 1.768 Å. It shows good agreement with the lattice constant found in bulk fcc Co ($a = 3.5447$ Å).⁶ The specular reflected RHEED intensity recorded during the deposition is shown in Fig. 1(a). RHEED intensity oscillation is observable with an average period of 1.8 Å. The oscillation means that fcc Co grows in a manner of layer-by-layer growth on the Cu(001) surface. However, the first, second, and third periods are longer than 1.8 Å. It is considered that the irregular oscillation periods with an initial decrease of intensity are due to cobalt agglomeration, which makes the growth mode deviate from the ideal layer-by-layer growth.^{7–9} Figure 1(b) shows the thickness dependence of the in-plane lattice constant estimated from intervals between (01) and (0 $\bar{1}$) streaks along [100] direction. Obviously, the first adsorbed Co layer has a different lateral lattice constant than that of the Cu substrate. The lattice constant for layers up to 20 Å thick takes a nearly constant value of 3.59 ± 0.01 Å, which is about 0.6% less than that for the Cu substrate and is also about 1.4% greater than that of the bulk fcc Co. Above 20 Å, the lattice constant approaches the intrinsic value of the bulk fcc Co asymptotically.

The Kerr effect was observed first at 6 Å (3.3 ML) with the in-plane easy axis. No perpendicular magnetic anisotropy was observed in the entire range of measurements. It agrees with other experimental results.^{5,10} The complex Kerr spectra for 6- to 20-Å-thick films exhibited essentially the same features. The Kerr ellipticity spectrum had a broad peak at around 4 eV. The Kerr rotation spectrum was correspondingly dispersive at the energy and had another broad peak at 4.8 eV. Figure 2 shows spectra of the off-diagonal elements of the conductivity tensor $\omega\sigma_{yz}$ for 20- and 1000-Å-thick fcc Co. The inset to Fig. 2 shows the $\text{Re } \sigma_{xx}$ spectra for those films. The conductivity tensor was calculated from the measured value of the complex Kerr effect $\phi_k + i\eta_k$ and the complex optical constant $n + ik$ using suitable equations. Apparently, there is a remarkable difference between the spectra

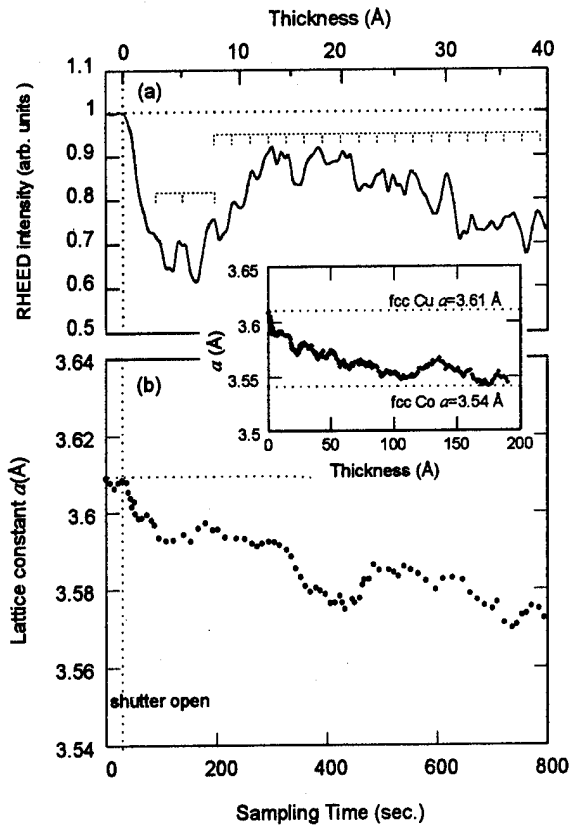

FIG. 1. (a) Specularly reflected RHEED intensity during the growth of Co films on Cu(001) surface. The electron beam is incident to 0.7° with an energy of 20 keV. The intensity is normalized to the value of the Cu surface. The upper horizontal axis shows the mass thickness of the film measured by the quartz thickness monitor. (b) Lateral lattice constant a as a function of the film thickness.

for 20-Å and 1000-Å-thick films. For 20-Å-thick film, the $\omega\sigma_{yz}$ spectra exhibit a resonance-type structure at around 5 eV. The $\text{Re } \omega\sigma_{yz}$ spectrum has a broad peak at around 4.8 eV. The $\text{Im } \omega\sigma_{yz}$ spectrum is correspondingly dispersive and changes its sign at 5.0 eV. On the other hand, for 1000-Å-thick film, the $\text{Im } \omega\sigma_{yz}$ still has not changed its sign at the energy. Theoretical calculations predicted that the $\text{Im } \omega\sigma_{yz}$ spectrum of bulk fcc Co took its sign, reversed from positive to negative, at 5.7 eV.¹¹ The interband transitions 1→6 in both spin bands are responsible for it.^{12–15} Halicov *et al.*¹¹ argued that the 1→6 transition was of the character for the 3d transition metals. The transitions occur between the s - d subbands located at the bottom of the 3d band and the higher s - p subbands above the Fermi level. Thus, the zero-crossing point of the $\text{Im } \omega\sigma_{yz}$ spectrum is roughly in proportion to the 3d-band width.

We consider that the marked resonance structure at 5 eV for 20-Å-thick film is caused by the same 1→6 transitions with shifting to the lower energy side due to the larger lateral lattice constant. Without any tetragonal distortion normal to the lattice planes, the larger lateral lattice constant causes a narrowing of the 3d-band width. Our RHEED experiments cannot provide any information about the perpendicular distances. However, recent low-energy electron diffraction analysis showed that the intermediate layers of Co/Cu(001)

FIG. 2. $\omega\sigma_{yz}$ spectra of Co films deposited on the Cu(001) surface. The solid and dotted-dashed curves correspond to 20- and 1000-Å-thick films, respectively. The inset shows the $\text{Re } \sigma_{xx}$ spectra of the films.

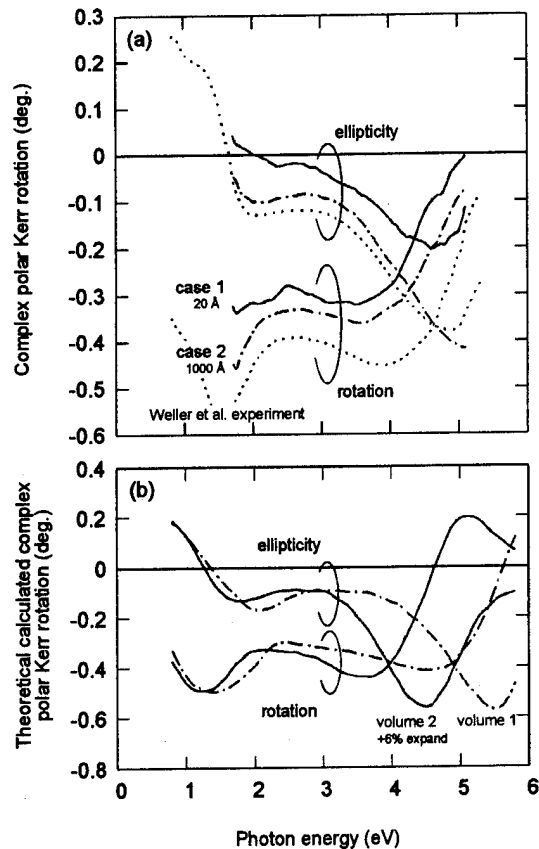

FIG. 3. (a) Evaluated complex polar Kerr spectra for bulk fcc Co. The solid and dotted-dashed curves correspond to cases 1 (using the conductivities for 20-Å-thick Co) and 2 (for 1000 Å), respectively. The dotted curves represent the experimental polar Kerr spectra for the 1000-Å-thick fcc Co film presented by Weller *et al.* (Ref. 3). (b) Theoretical calculated spectra for bulk fcc Co presented by Gasche *et al.* (Ref. 17). The solid and dotted-dashed curves correspond to volumes 1 (11.18 Å/atom), and 2 (13.22 Å/atom; 18% expanded compared with volume 1), respectively.

films that were a few monolayers thick had an interlayer spacing of 1.74 ± 0.01 Å, a decrease by about 2% compared with the bulk fcc Co.^{9,16} If we obediently combine the value of $c=3.48$ Å with the lateral lattice constant $a=3.59$ Å, we get a value of 11.21 Å³/atom as the atomic volume. It is increased by about 1% compared with that of the bulk fcc Co ($a=3.54$ Å; 11.09 Å³/atom).

Recently, Gasche *et al.*¹⁷ calculated the complex polar Kerr spectra of the bulk fcc Co as a function of the lattice parameter. In order to compare our results with their theoretical calculations, we evaluated the complex Kerr spectra of the bulk fcc Co from the obtained conductivities. In Fig. 3(a) the evaluated polar Kerr spectra are shown. Cases 1 and 2 correspond to the 20- and 1000-Å-thick Co, respectively. The dotted lines show the experimental result for the 1000-Å-thick fcc Co film presented by Weller *et al.*³ It is clearly seen that the high energy peak in the ellipticity spectrum in case 2 shifts to lower energy compared to the peaks of case 1 and Weller's data. Figure 3(b) shows the theoretical calculations by Gasche *et al.*¹⁷ In the calculation, they took volumes 1 and 2 to be 11.18 and 13.22 Å³/atom, respectively. The former corresponds to the experimental lattice constant of $a=3.54$ Å and the latter to the case where the lattice constant is 6% larger than that of the experiment. The ellipticity spectrum for volume 1 shows a broad peak at 5.4 eV. And strikingly, the high energy peak shifts to the low energy side at about 4.4 eV for volume 2. They also calculated the magnetic moments for each case. It was shown that the 18% expansion in atomic volume caused a 10% enhancement in the magnetic moment. Their results clearly confirmed that the center position of the 1→6 transitions strongly depends on the 3d-band width. From these results, it is satisfactory to say that the observed lateral lattice expansion in the 20-Å-thick Co may modify the electronic structure, narrowing the 3d-band width, as it appears to effect its magneto-optical properties.

In conclusion, in the 20-Å-thick fcc Co film, we found that the $\text{Im } \omega\sigma_{yz}$ spectra for the 20-Å-thick film changed its sign at 5 eV. Theoretical calculations predicted that the $\text{Im } \omega\sigma_{yz}$ spectrum of bulk fcc Co took its sign, reversed from positive to negative, at 5.7 eV. It is considered that the observed lower energy shift of the zero-crossing point of $\text{Im } \omega\sigma_{yz}$ is due to the expanded lateral lattice constant that leads to the narrowing of 3d bands.

We explore the magnetic interlayer exchange coupling in single-crystalline Fe/Cr and Co/Cu wedged multilayers prepared by magnetron sputtering on two orientations of MgO—(100) and (110). Structural examination shows that high quality epitaxial films are obtained in both systems using seeded epitaxy growth techniques. Oscillatory interlayer coupling is observed in Cr-wedged samples grown on both MgO(100) and MgO(110) with similarly long oscillation periods of ~ 18 Å. These results are comparable to earlier work for molecular beam epitaxy and sputter-deposited epitaxial Fe/Cr structures. Long-period oscillatory coupling is also observed in sputtered Co/Cu(110) for the Cu-wedged structures. Studies of the dependence of magnetic coupling on the thickness of the magnetic layers for fixed Cr layer thickness provides no evidence of any nonmonotonic dependence. © 1996 American Institute of Physics. [S0021-8979(96)71808-2]

Since the discovery of antiferromagnetic (AF) coupling between ferromagnetic layers across a nonmagnetic spacer layer¹ and its oscillatory nature,² interlayer exchange coupling has attracted extensive theoretical and experimental studies for a wide variety of structures. Oscillation in exchange coupling as a function of nonmagnetic layer thickness has been demonstrated to be a general property for most magnetic/nonmagnetic transition and noble-metal multilayers.³ Long periods of 8–12 Å—with the exception of Cr (~ 18 Å)—have been identified in sputtered polycrystalline multilayers.³ Additional short-period oscillations have been found in molecular-beam epitaxy (MBE) grown single-crystalline wedges.^{4,5} Of particular interest is the dependence of the interlayer exchange coupling strength on the thickness of the ferromagnetic layer. There have been far fewer studies on this property and the nature of this dependence, whether oscillatory^{6,7} or not, remains an open question.

Sputter epitaxy is a useful technique for the growth of oriented epitaxial films since it readily allows for the exploration of diverse materials and thin film structures. This technique has had limited application to the study of the magnetic and transport properties of epitaxial metallic thin film structures.^{8–10} In this article, we study the interlayer exchange coupling in wedged Fe/Cr(100), (211), and Co/Cu(110) sandwiches and multilayers prepared by magnetron sputtering. Results are presented for well-defined long-period oscillations in wedged structures as well as the consequences of significant in-plane magnetic anisotropy. These studies were, in large part, carried out using longitudinal magneto-optical Kerr measurements.

A number of Fe/Cr and Co/Cu wedged multilayers, with either a wedged nonmagnetic layer or ferromagnetic layers, were grown by magnetron sputter deposition in an ultrahigh vacuum chamber equipped with six 2 in. dc magnetron sputtering sources. The base pressure prior to deposition was typically 2.0×10^{-9} Torr, the sputter pressure was usually 3.0×10^{-3} Torr Ar and the deposition rates were 2.0 Å/s for all sputtered metals. For Fe/Cr, a Cr seed layer, at least 100

Å thick was deposited at temperatures ranging up to 525 °C onto polished, chemically cleaned single-crystal MgO(100) and (110) substrates to establish the epitaxy. Subsequent layers were deposited at 150–180 °C and were capped with a thin Cr layer. For Co/Cu a seed layer of 50 Å Pt was deposited at 500–525 °C and the Co/Cu structure was grown near room temperature. The wedged layers were formed by moving a precision-controlled shutter during the deposition. Usually related nonwedged multilayers with fixed layer thicknesses were deposited under similar conditions to allow for detailed x-ray and superconducting quantum interference device magnetometry studies. The structural characterization of the films was performed using x-ray diffraction with Cu K_α radiation. The magnetic properties were studied with longitudinal magneto-optic Kerr effect (MOKE). Using computer-controlled precision motion stages Kerr hysteresis loops were collected as a function of position along a wedge and azimuthal orientation of the wedge with regard to the applied magnetic field.

The crystallographic orientation of the films was examined by x-ray diffraction on nonwedged multilayer samples. Figure 1 shows the high-angle specular θ – 2θ scan for a [Fe15 Å/Cr 28 Å]₇ multilayer grown on 100 MgO. Figure 1 also shows that the film is of a single-crystallographic orientation and is oriented along (100). Only the MgO(200), MgO(400), and Fe/Cr(200) reflections and the associated superlattice satellites are observed. The Fe/Cr(200) rocking curve full width at half-maximum (FWHM) is only 1.30° as shown in the inset of Fig. 1, indicating a high degree of crystal orientation. The high-angle specular scan for a corresponding Fe/Cr multilayer grown on 110 MgO similarly shows evidence of a single-crystalline orientation. In this case Bragg peaks corresponding to MgO(220) and Fe/Cr(211) and its associated superlattice peaks are found. Rocking curves about the Fe/Cr(211) reflection have a typical FWHM of 1.40°. These values compare favorably with rocking curves from typical comparable MBE-grown

FIG. 1. High angle x-ray specular scan for a Fe/Cr multilayer of the form, MgO(100)/Cr 100 Å/[Fe 15 Å/Cr 28 Å]₇/Fe 15 Å/Cr 40 Å. The inset shows the rocking curve at the Fe/Cr(200) Bragg reflection.

multilayers.¹¹ The in-plane structure and epitaxial orientation were also studied by asymmetric diffraction scans on selected samples.

As an indirect structural characterization, we studied the magnetocrystalline anisotropy on a wedged multilayer to verify its epitaxial crystal structure. Such an experiment was carried out by measuring the MOKE hysteresis loops at a particular Cr thickness for which the magnetic layers are ferromagnetically coupled for various azimuthal angles. Figure 2 shows the dependence of the in-plane remanent magnetization as a function of azimuthal angle for typical (100)- and (211)-oriented Fe/Cr samples. The remanent moment is defined as a proportion of the saturation magnetization of the film. The remanence will show maxima along the easy axis and minima along the hard axis. As shown in Fig. 2 the (100)-oriented sample displays a fourfold magnetic anisotropy, whereas the (211)-oriented sample has a twofold mag-

FIG. 2. The dependence of remanent magnetization as a function of azimuthal angle for wedged Fe/Cr multilayers with Cr thickness ~ 20 Å, for (100) orientation, and (211) orientation.

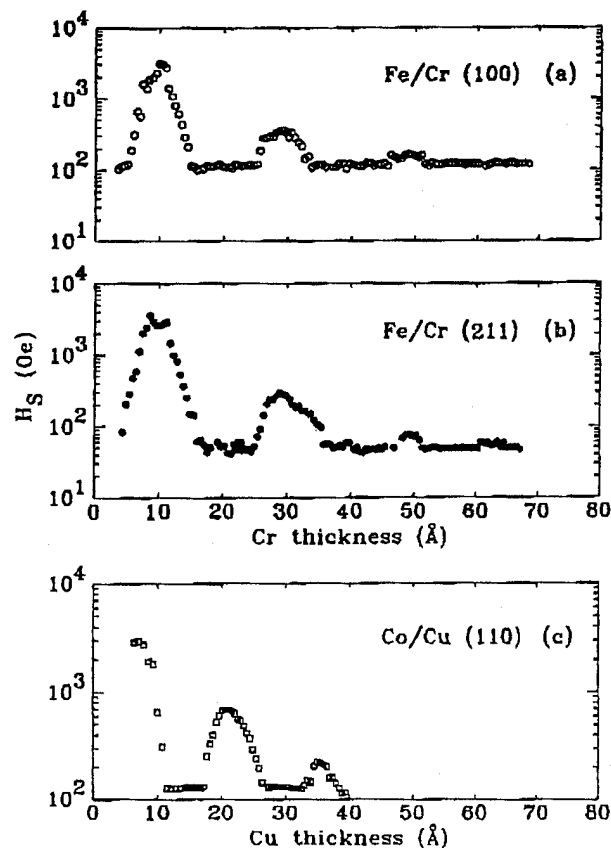

FIG. 3. The dependence of saturation (75%) field H_s on the nonmagnetic layer thickness for: (a) MgO(100)/Cr 100 Å/[Fe 15 Å/Cr (4–70) Å]₅/Fe 15 Å/Cr 40 Å; (b) MgO(110)/Cr 100 Å/[Fe 15 Å/Cr (4–70) Å]₅/Fe 15 Å/Cr 40 Å; and (c) MgO(110)/Pt 100 Å/Cu 50 Å/[Co 10 Å/Cu (5–40) Å]₅/Co 10 Å/Cu 10 Å/Pt 15 Å.

netic anisotropy as expected from the corresponding crystal symmetries. The dashed lines shown in Fig. 2 are straightforward calculations of the idealized remanence, which is proportional to the cosine of the angle between the measurement direction and the nearest easy axis.^{9,12} For the (211) oriented multilayer there is excellent agreement between the calculated and measured remanence indicative of a strong in-plane uniaxial anisotropy. For the 100 sample slight deviations from the calculated curve may be due to the finite coercivity of the film.⁹

The interlayer exchange coupling was investigated at room temperature by measuring magnetic hysteresis loops at various positions along a wedge using the MOKE magnetometer. Fe/Cr and Co/Cu wedged structures were studied for which either the nonmagnetic layer Cr and Cu layer thicknesses or the ferromagnetic layer Fe and Co thicknesses were varied. In order to enhance the Kerr signal the structures were multilayered and typically comprised five wedged layers. Figure 3 shows typical plots of the saturation field as a function of nonmagnetic layer thickness for Fe/Cr(100), (211) and Co/Cu(110). The saturation field is defined arbitrarily as the field at which the moment corresponds to 75% of the saturation magnetization, except where otherwise specified. To properly include effects of in-plane crystalline anisotropy the angular dependence of the magnetic properties was first explored to find the magnetic easy and hard

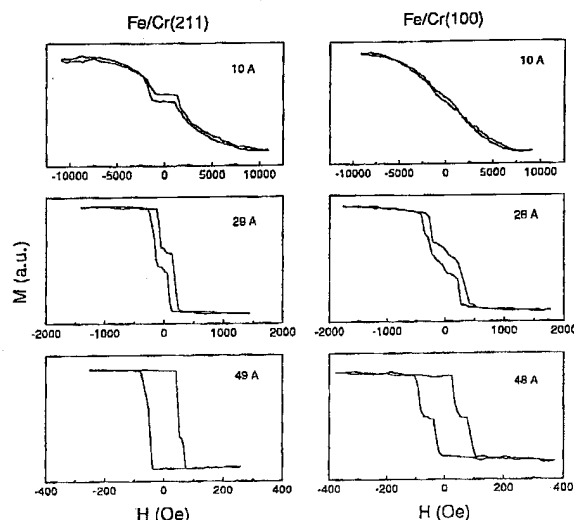

FIG. 4. Typical MOKE hysteresis loops for sputter-epitaxy grown (110) and (100) Fe/Cr wedged multilayers at the first three AF-coupled Cr peak positions. The samples are the same as those shown in Figs. 3(a) and 3(b).

axes. Scans along the wedge were subsequently performed along these or related directions which correspond to particular crystal directions. The MOKE apparatus allows the sample to be placed at an arbitrary angle with respect to the external field. As shown in Figs. 3(a) and 3(b), three well-defined peaks in the saturation field are observed for Fe/Cr(100) and Fe/Cr(211) wedged multilayers at room temperature. Note that each set of data in Fig. 3 was obtained from two wedged samples which span successive Cr thickness ranges for each orientation. An expected long-period oscillation with a Cr period of ~ 18 Å is found. For both orientations, the coupling strength and phase are nearly identical, and are similar to previous results found for epitaxial Fe/Cr structures.^{4,8} Although no clear short-period oscillations are seen for these sputtered wedges, there is structure (a twin peak) within the first and second peaks shown in Fig. 3 which may be associated with the presence of a short-period oscillatory coupling. Figure 3(c) shows the saturation field as a function of Cu thickness for an epitaxial Co/Cu(110) wedged multilayer. Three peaks in the saturation field are readily identified in a single-wedged multilayer corresponding to an oscillation period similar to that found in MBE-grown Co/Cu wedges.⁵

Figure 4 shows typical room-temperature magnetic hysteresis loops measured on 100 and (211) Fe/Cr wedged multilayers at three Cr thicknesses (10, 29, and 48 Å) corresponding to the three AF peaks in Figs. 3(a) and 3(b). Note that the corresponding 100 and (211) samples were deposited simultaneously on substrates placed side by side to ensure otherwise identical samples. The hysteresis loops are measured along the in-plane magnetic easy axes for each orientation. The shape and detailed structure of the magnetic hysteresis loops reflects a competition between the AF interlayer coupling between the Fe layers and the magnetic anisotropy of the Fe layers. As the Cr thickness is increased the AF

coupling strength decreases rapidly, whereas the anisotropy varies less. Depending on the relative strength of the AF coupling and the magnetic anisotropy a spin-flop transition is observed in some cases, as evidenced by an abrupt change in the magnetization at a particular field. Similarly a plateau in magnetization for the (211)-oriented Fe/Cr wedges at low fields results from a large in-plane magnetic anisotropy compared to strength of the AF coupling. The different shapes of the hysteresis loops for the (211) and 100 samples suggest that the in-plane magnetocrystalline anisotropy is weaker for the (100)-oriented samples as compared to that of the (211) orientation. The magnetization behaviors for these oriented wedge structures are similar to these found for oriented superlattices.⁸

Using high quality crystalline wedged multilayers the dependence of the AF coupling strength on the ferromagnetic layer thickness has been explored for a number of structures. In contrast to recent results from Fe/Cr multilayers grown by ion beam sputtering,⁶ our data show no clear evidence of an oscillatory dependence of coupling strength on the thickness of Fe, t_{Fe} , in 100 Fe/Cr structures. By contrast, the saturation field, H_S , is found to decrease monotonically with increasing Fe thickness simply as $1/t_{\text{Fe}}$. The same functional dependencies of H_S on $1/t_{\text{Fe}}$ were found in a series of 100 Fe/Cr superlattices prepared by similar sputter epitaxy techniques.¹³

The current study demonstrates that sputter epitaxy is a technique capable of producing a wide range and large number of structures quickly and relatively inexpensively. This allows the ready exploration of magnetic and other properties which are sensitive to crystal orientation. It is particularly useful to prepare high quality single-crystalline wedged structures which, as previously demonstrated in MBE studies, can be quickly measured using simple Kerr magnetometry allowing the extraction of both interlayer coupling strengths and in-plane magnetic anisotropies.

By combining MCXD experiments with first principles electronic structure calculations, we demonstrate that the orbital contribution to magnetism can be strongly enhanced at surfaces. This effect is illustrated for Co grown on a Cu(100) surface. The MCXD measurements were performed using the SX 700 plane grating monochromators at BESSY. The Co films were evaporated and characterized *in situ*, for their cleanliness, thickness (1.6–50 ML), and structural order.¹ For a film thickness up to 2.2 ML, measurements of the ac MCXD susceptibility response at a fixed photon energy allowed one to measure the critical temperature, T_c , of the films and their critical properties were characterized *in situ*.¹ For several samples the MCXD response as a function of the x-ray incidence angle was investigated as well. This allows one to quantify and correct saturation effects that can occur in the measurements.² Data were taken in a temperature range between 40 and 350 K, and for many samples measurements were performed at several reduced temperatures, T/T_c . The first layer of Co on the Cu(100) surface shows an enhanced orbital moment, in contrast to the subsequent layers where the orbital moment is bulklike. The lowering of the symmetry, the enhanced spin moment, and the increased value of the density of states at the Fermi level are factors that combine to give the observed enhancements. © 1996 American Institute of Physics.

Critical phenomena in the two-dimensional XY magnet Fe(100) on W(100)

H. J. Elmers, J. Hauschild, G. H. Liu, and U. Gradmann
Physikalisches Institut, TU Clausthal, D 38678 Clausthal-Zellerfeld, Germany

We experimentally investigated the magnetic phase transition of the in-plane magnetized double-layer Fe on W(100). This epitaxial system approximates the theoretical two-dimensional (2D) XY model to a large extent because of its pseudomorphic growth and structural stability. We measured the magnetization of W(100)/Fe in the vicinity of the Curie temperature T_C using the diffraction of spin polarized electrons and the magnetization of W(100)/Fe/Ag in a wider temperature interval using conversion electron Mössbauer spectroscopy. The temperature dependence of the spontaneous magnetization follows a power law with an exponent $\beta=0.22\pm0.03$ in the temperature regime $0.3\leq T/T_C\leq 0.99$. The susceptibility $\chi(T>T_C)$ can be fitted alternatively by a power law with an unusually large exponent $\gamma\approx 5$ or by an exponential law $\chi\propto\exp(b/\sqrt{T-T_C})$, as predicted for the 2D XY model, with $b=1.6$. © 1996 American Institute of Physics. [S0021-8979(96)71908-9]

The magnetic phase transition in ultrathin films of two-dimensional (2D) symmetry is a subject of intensive research. Whereas the Mermin-Wagner theorem¹ predicts an absence of long range order in isotropic 2D systems, a magnetic second-order phase transition has been found in several ultrathin films on nonmagnetic substrates.²⁻⁴ One generally believes that the magnetic anisotropy is responsible for the existence of magnetic order in these ultrathin films. For an anisotropy of twofold (uniaxial) symmetry theoretical considerations result in a phase transition which has the character of the well-known 2D Ising model.^{5,6} For in-plane magnetized films in the (100) crystallographic orientation it is easy to show that the twofold anisotropy term vanishes. The character of phase transition in these films without uniaxial anisotropy is not well understood. Whereas the persistence of the 2D XY model, if anisotropies of sixfold symmetry are included, is a matter of fact,⁷ it is a guess for the fourfold case. The 2D XY model on a lattice of infinite size predicts an absence of spontaneous order.⁸ Recently, Bramwell and Holdsworth⁹ suggested that finite size effects can stabilize magnetic order in the 2D XY model. Experiments on ultrathin magnetic films approximating the theoretical model are of particular interest as they can test the theoretical predictions.

Experimental studies of ultrathin films approximating the 2D XY model (i.e., in-plane magnetization without uniaxial anisotropy) Au(100)/Fe(100),^{10,11} Cu(100)/Ni(100),¹² and Cu(111)/Ni(111)¹³ confirm the effective exponent $\beta=3\pi^2/128\approx 0.23$, predicted in Ref. 9. Considerable errors (>20%) for the magnetization exponent show up in previous studies,^{11,13} which in part might be caused by structural defects. The critical behavior of the magnetic susceptibility has not been analyzed yet for this class of ultrathin films.

In this article we study the bilayer Fe(100) on W(100). We choose this system because the structure approximates theoretical model systems to a large extent. The free surface enthalpy of W $\gamma_W=3.4\text{ J m}^{-2}$ is larger than that of Fe $\gamma_{Fe}=2.9\text{ J m}^{-2}$. Therefore the Fe adsorbate wets the W substrate, forming thermodynamically stable and pseudomorphic films consisting of large area islands. A detailed structural study of the bilayer Fe(100) on W(100) is given in Refs.

14 and 15. In contrast to the case of noble metal substrates the *d*-band electrons of Fe and W hybridize to some extent. *Ab initio* calculations¹⁶ result in magnetic moments of Fe atoms directly at the W interface ($1.7\mu_B/\text{atom}$) and Fe atoms in the second layer ($2.4\mu_B/\text{atom}$), whereas the polarization of W atoms at the interface ($-0.2\mu_B/\text{atom}$) is negligible. We present experimental data both for the spontaneous magnetization and for the magnetic susceptibility. We will show that the experimental data are consistent with the theoretical picture of the 2D XY model given in Ref. 9. Two sets of experiments were performed in separate vacuum chambers with similar preparation conditions. The spontaneous magnetization of the Ag-covered bilayer Fe on W(100) was determined using conversion electron Mössbauer spectroscopy (CEMS).¹⁷ The magnetization as a function of temperature and external field for the uncovered W(100)/Fe(100) bilayer was investigated by spin polarized low-energy electron diffraction (SPLEED).^{15,18}

Using CEMS in zero external field¹⁷ we measured the magnetic hyperfine field $B_{hf}(T)$ as a function of temperature for the Ag-covered Fe bilayer on W(100). B_{hf} measures the local spontaneous magnetization independent of the magnetic domain state and is proportional to the magnetization with respect to its temperature dependence even far away from T_C .¹⁹ Results of $B_{hf,i}(T)$ for a Fe film of thickness $\Theta=2.2$ monolayers (ML) deposited at 300 K are plotted in Fig. 1. Below T_C , the CEMS spectra of the double layer showed three components of different hyperfine fields $B_{hf,i}=a-c$. The three components belong to Fe atoms placed in different atomic environments.²⁰ Fe atoms directly at the W surface and covered by Fe atoms (a) produce component $B_{hf,a}$. Fe atoms in the second layer and covered by Ag (b) produce component $B_{hf,b}$. Finally, Fe atoms in the second layer and covered by Fe atoms or Fe atoms in the third layer (c) produce the component $B_{hf,c}$. Figure 1 shows power law fits to the temperature dependence of the three components. All three components show the same temperature dependence and can be fitted in the total available temperature interval $88\text{ K}\leq T\leq T_C$ by a power law $B_{hf,i}(T)=B_{hf,i}(0)(1-T/T_C)^\beta$ with the same Curie temperature $T_C=306\text{ K}$ and the same effective exponent $\beta=0.22\pm0.01$. The common

FIG. 1. Temperature dependence of the magnetic hyperfine field B_{hf} for a film of Fe(100) on W(100) having a thickness of $\Theta=2.2$ ML, deposited at $T_p=315$ K, and coated by Ag. The spectra consists of three components, corresponding to Fe atoms at the Fe/W interface [(a), Δ], Fe atoms in the second layer at the Fe/Ag interface [(b), \square], and Fe atoms in the second or third layer of triple-layer islands [(c), \bullet]. The solid lines represent power law fits with a unique Curie temperature $T_C=306$ K and critical exponent $\beta=0.22\pm0.01$.

temperature dependence allows the conclusion that no magnetically independent clusters exist in the sample (i.e., monolayer and double-layer patches) and that no spin-wave components perpendicular to the film with a wave vector $k_{\perp} \neq 0$ are excited. Hence the magnetic behavior of the double layer is truly 2D.

For the uncovered bilayer Fe on W(100) we measured the magnetization $M(H,T)$ as a function of external magnetic field ($H < 2$ Oe) and temperature T using SPLEED (see Refs. 15 and 18). With this method one determines the asymmetry $P_0 A_{ex}$ of specular reflected electrons for spin polarization $|\mathbf{P}_0|=0.2$ parallel or antiparallel to the direction of magnetization.²¹ $P_0 A_{ex}$ shows the same temperature and field dependence as the magnetization component M along the quantization axis.^{11,22} The quantization axis was directed along one of the two in-plane easy axes—[001] or [010].²³ In contrast to the temperature dependence of the hyperfine field $B_{hf}(T) \propto M(T)$, the proportionality $P_0 A_{ex}(H,T) \propto M(H,T)$ only holds in the direct vicinity of T_C , i.e., for reduced temperature ($|t|=|1-T/T_C| < 0.1$). Figure 2 shows the experimental results for the temperature dependence of $P_0 A_{ex}(0,T)$ of a Fe film having a thickness of $\Theta=1.6$ ML, deposited at 300 K and subsequently annealed at 550 K. We observed a reversible temperature dependence of $P_0 A_{ex}(T)$. Therefore we conclude that the film stays in a homogeneous single-domain magnetic state. A single-domain state is not uncommon for ultrathin films of the (100) symmetry class. Single-domain states were observed directly by SEMPA studies for Co/Cu(100).²⁴ For a single-domain state $P_0 A_{ex}(H=0,T)$ is proportional to the spontaneous magnetization. We fitted our data to the power law $P_0 A_{ex}(T) \propto (1-T/T_C)^{\beta}$ in the temperature interval $0.9 \leq T/T_C \leq 0.99$ with T_C and β as fitting parameters. The fit interval is limited by the onset of the tail at $T=0.99T_C$, where the experimental data deviate considerably from the power law (see Fig. 2). This frequently observed tail above T_C is attributed to finite size effects which broaden the transition. Note that the tail covers a temperature region of $\Delta T/T_C \approx 0.5\%$ only. Usually 3%–5% of the tails are observed for ultrathin films.³ The theoretical value for the tail width is $\Delta T/T_C \approx a/l$,³ where a is the lattice parameter

FIG. 2. Exchange asymmetry $P_0 A_{ex}(T)$ (\bullet) in the remanent state for a film of Fe(100) on W(100) having a thickness of $\Theta=1.6$ ML, deposited at 300 K and subsequently annealed at $T=550$ K. The power law ($P_0 A_{ex} \propto (T_C - T)^{\beta}$ [$\beta=0.217 \pm 0.002$, $T_C=(207.8 \pm 0.1)$ K]) is fitted in the interval $[0.9T_C, 0.99T_C]$. The inset shows $P_0 A_{ex}(T)$ and the increase of asymmetry $\Delta P_0 A_{ex} = P_0 [A_{ex}(H,T) - A_{ex}(0,T)]$ for external field $H_1=0.63$ Oe (\circ). The exponential law $\Delta P_0 A_{ex} \propto \exp(b/\sqrt{T/T_C - 1})$ (solid line) was fitted to the data for fixed $T_C=207.8$ K, resulting in $b=1.6$.

and l is the length scale of the coherent regions of the film. This implies a finite size scale of $l \approx 400$ Å. The power law fit results in $T_C=207.8$ K and $\beta=0.217 \pm 0.002$. The power law is further characterized by the straight line of data points in a log-log plot (see Fig. 3).

It should be mentioned that the statistical error of β from the fit (0.1%) is far less than the variance resulting from deviating temperature intervals used for the fit.³ Since the critical region for which the power law should be valid is not known exactly we varied the fit interval within reasonable limits (see Ref. 3). Taking into account this uncertainty, we finally attain $\beta=0.22 \pm 0.03$. We performed similar fits for three films in the thickness region $1.6 \text{ ML} \leq \Theta < 2.0 \text{ ML}$, resulting in a unique value of the effective exponent $\beta=0.22 \pm 0.03$, which we then identify with the unique exponent of the double layer.

The magnetic susceptibility was derived from the field dependence of the asymmetry, $\chi(T) \propto \Delta P_0 A_{ex}(H,T)$, where $\Delta A_{ex}(H,T) = A_{ex}(H,T) - A_{ex}(0,T)$. $\Delta A_{ex}(H,T)$ was mea-

FIG. 3. Double logarithmic plot of susceptibility $\chi(\circ)$ and spontaneous magnetization $M(\bullet)$ vs reduced temperatures (data from Fig. 2). The full lines represent fits to the power law and to the exponential law, respectively (see Fig. 2).

sured for $H_1=0.6$ Oe and $H_2=1.3$ Oe. Figure 2 shows the experimental data of $\Delta P_{0A_{ex}}(H_1, T)$ for the same bilayer as discussed above.

In a temperature regime directly at T_C , $0.98 < T/T_C < 1.02$, the difference $\Delta A_{ex}(H, T)$ showed a sublinear increase with H . In this temperature regime $\Delta A_{ex}(H, T)$ provides a lower limit for $\chi(T)$, only. We find a maximum value of $\Delta A_{ex}(H, T)$ at $T=210$ K $= 1.01T_C$. A direct determination of the absolute value of χ is not possible. However, a rough estimate can be made by deriving the proportionality constant $\alpha = M/P_{0A_{ex}}$ from the low temperature extrapolation. Then the lower limit for the susceptibility maximum is $\chi(1.01T_C) > 1 \times 10^4$ (in SI units). Following Farle *et al.*,²⁵ $\chi = l/t$ can be related to the length scale l of homogeneous islands in the film of thickness t . In this model the maximum value of χ would correspond to $l > 30 \mu\text{m}$ in sharp contrast to the small value of l estimated from the tail of $M(0, T)$. We would rather guess that the giant susceptibility is an indication of a structurally induced superparamagnetic susceptibility, as discussed for Fe films on W(110).²⁶

For $T > 1.02T_C$, we observed a linear increase of $\Delta A_{ex}(H, T)$ with H , resulting in the temperature dependence of $\chi(T)$. Figure 3 shows a double logarithmic plot of $\chi(T > 1.02T_C)$ using $T_C = 207.8$ K. The logarithmic plot reveals the steep increase of $\chi(T)$ upon approaching T_C from the paramagnetic region. Assuming a power law divergence $\chi(T) \propto (T - T_C)^{-\gamma}$, the linear section of the slope would correspond to an unusually large value of the exponent $\gamma \approx 5$. Instead we show in Fig. 3 a fit using the exponential law predicted for the 2D XY model, $\chi(T) \propto \exp(b/\sqrt{T/T_C - 1})$.⁸ The fit results in the parameter $b = 1.6 \pm 0.1$, which is of the order of magnitude predicted for the pure 2D XY model ($b = 2.6$).⁸ Note that $\chi(T)$ also increases considerably upon approaching T_C from temperatures below T_C .

In summary we measured the critical behavior of the spontaneous magnetization and of the magnetic susceptibil-

ity for the double-layer Fe(100) and W(100). Our results are consistent with a finite size 2D XY model. A quantitative comparison of theory and experiment obviously requires further research involving experimental samples and theoretical models.

***In situ* Brillouin light scattering from ultrathin epitaxial Fe/Ag(100) films with Cr and Ag overlayers**

R. J. Hicken, A. Ercole, S. J. Gray, C. Daboo, and J. A. C. Bland
Cavendish Laboratory, Madingley Road, Cambridge CB3 0HE, United Kingdom

We have studied the magnetic properties of ultrathin epitaxial Fe/Ag(100) films by means of *in situ* Brillouin light scattering (BLS) in an ultrahigh vacuum chamber equipped with magneto-optic Kerr effect, low energy electron diffraction, and reflection high energy electron diffraction instruments. Our novel *in situ* BLS system allows us to perform measurements rapidly, in order to avoid surface contamination, and hence to observe the evolution of the spin-wave frequency with increasing film thickness. Good reproducibility is observed between different growth runs. The direction of the applied field within the film plane has been varied revealing that the magnetocrystalline anisotropy has cubic symmetry and that there is no observable in-plane uniaxial anisotropy. From the values of the hard and easy axis spin wave frequencies we have determined the values of the in-plane fourfold anisotropy and effective demagnetizing fields during the growth of 13.9 monolayer (ML) Fe films. The evolution of the fourfold anisotropy is in reasonable agreement with that reported by other researchers. The effect of depositing Cr and Ag overlayers onto the completed 13.9 ML film has also been studied. We have deduced values for the surface anisotropy constants for the Fe/Ag and Fe/vacuum interfaces and we compare these with previously reported values. A qualitatively different evolution of the spin wave frequency with overlayer thickness is observed for the deposition of Cr and Ag, which may be related to the magnetic properties of the Cr overlayer. © 1996 American Institute of Physics. [S0021-8979(96)72008-3]

We have recently developed a novel *in situ* Brillouin light scattering (BLS) apparatus that allows us to make measurements both quickly and routinely during the growth of ultrathin film samples. In this paper we report first upon our results for the growth of epitaxial Fe films on Ag(100) substrates and second upon the effect of depositing Ag and Cr overlayers on to 13.9 monolayer (ML) thick Fe layers. Both the cubic magnetocrystalline and surface anisotropy constants may be determined as the film thickness is increased in submonolayer steps. It is well known that high quality epitaxial Fe(100) films can be stabilized on the Ag(100) substrate and an excellent review of the structural and magnetic properties of this system has recently been given.¹ The growth of the first few ML of Fe was found to be complicated and subject to the detailed growth conditions. As the Fe thickness, d , is increased the magnetization reorients from an out of plane to an in-plane configuration and there is some variation in the value of d at which the magnetization reorientation has been reported to occur.¹⁻³ However it is believed that as d is increased above a value of about 5 ML a stable growth mode is obtained.¹

A value of $d=13.9$ ML was chosen for experiments in which overlayers of either Ag or Cr were deposited because the magnetic properties of the completed Fe layers were found to be well reproduced between different growth runs and because the measured spin wave frequencies were found to still be sensitive to the overlayer coating. The use of Ag overlayers allows us to obtain symmetric boundary conditions for the Fe film and hence to determine the values of the surface anisotropy constants for both the Fe/vacuum and Fe/Ag interfaces. The use of Cr is motivated by the recent observation of a large moment in Cr overlayers and by the fact that the ordering of successive layers of Cr moments in the ultrathin limit is subject to debate.⁴ We show here that Ag

and Cr overlayers have a qualitatively different effect on the magnetic properties of the underlying Fe layer.

The commercially obtained single crystal Ag(100) substrate was mechanically polished and then chemically polished and electropolished. Cycles of 500 eV Ar⁺ sputtering and annealing were used to clean the substrate and to remove the deposited film at the end of each growth run. The base pressure in the chamber was better than 2×10^{-10} mbar, rising to no more than 5×10^{-10} mbar during deposition. Reflection high energy electron diffraction (RHEED) intensity oscillations were observed during the homoepitaxial growth of Ag on our crystal. This allowed us to calibrate a quartz crystal oscillator placed in the sample position and the Fe and Cr rates were then calibrated using this same crystal oscillator. Deposition of the Fe, Ag, and Cr was carried out at ambient temperature using a typical rate of 1 Å per minute. Figure 1 shows typical RHEED patterns obtained from the surfaces of a clean Ag crystal and a 13.9 ML Fe film. These show that the substrate is flat and well ordered and confirm the epitaxial nature of the Fe film. A detailed structural study using low energy electron diffraction (LEED) and RHEED will be described elsewhere.

We are able to perform both BLS and longitudinal magneto-optic Kerr effect (MOKE) measurements *in situ* without moving the sample from the main growth position. Instead a Fe core electromagnet with a maximum field of 2.1 kOe is moved so that the sample lies between its pole pieces. The sample holder possesses azimuthal rotation so that the magnetic field may be applied along any direction within the plane of the film. The novel feature of the BLS system is that the $f/\text{No. } 2$ objective lens is located in a re-entrant tube, mounted on a bellows, that can be moved close to the sample whenever it is required. Further details of our system will be given elsewhere.

FIG. 1. Negative RHEED images at a beam energy of 15 keV and angle of incidence of $\sim 3^\circ$ are shown for (a) the Ag(100) substrate, and (b) a 13.9 ML Fe(100) film. The beam direction indicated in each case corresponds to a crystallographic axis of the Ag substrate.

For Fe layer thicknesses greater than 3 ML we find, from MOKE and BLS measurements, that the magnetic anisotropy is fourfold with any in-plane uniaxial anisotropy being negligibly small. The magnetic free energy per unit area of the Fe(100) film may be written in the form

$$E = d[-\mathbf{M} \cdot \mathbf{H} + K_1^\parallel(u_x^4 + u_y^4) + K_1^\perp u_z^4 + 2\pi DM^2 u_x^2] + (K_s^{(1)} + K_s^{(2)})u_x^2, \quad (1)$$

in which u_x, u_y , and u_z are the direction cosines of the magnetization, \mathbf{M} , relative to the crystallographic axes of the film, with the x axis being taken as the surface normal. \mathbf{H} is the applied magnetic field vector, K_1^\parallel and K_1^\perp are the magnetocrystalline volume anisotropy constants,¹ and $K_s^{(1)}$ and $K_s^{(2)}$ are the surface anisotropy constants for the two surfaces of the film. If the magnetization lies in the film plane, as is the case in this study, then in-plane MOKE and BLS are sensitive only to the value of K_1^\parallel and so we will refer to the value of K_1^\parallel simply as K_1 . A factor D has been included in the demagnetizing energy term to take account of the reduced demagnetizing field that occurs in ultrathin films due to the discrete nature of the lattice. We have taken D to have the form $1 - 0.425/N$ where N is the thickness of the Fe film in monolayers.¹ We have not included a volume type uniaxial perpendicular anisotropy energy in Eq. (1) because this is believed to be negligible for Fe/Ag(100).¹

Enhanced moments in ultrathin Fe/Ag(100) films have been both predicted⁵ and observed.⁶ However, since we are not able to measure the Fe moment directly *in situ*, in this study we assume that the Fe magnetization is thickness independent and equal to the bulk value of 1710 emu/cm³. All BLS calculations also assume the bulk Fe values of 2.09 for the g factor and 2×10^{-6} erg/cm for the exchange constant. The spin wave frequencies observed by BLS are determined largely by the values of two quantities, the cubic anisotropy field $2K_1/M$ and the effective demagnetizing field

$$(4\pi M)_{\text{eff}} = 4\pi DM - 2(K_s^{(1)} + K_s^{(2)})/Md. \quad (2)$$

By measuring the spin wave frequency with the field applied parallel to the easy [001] and hard [011] in-plane

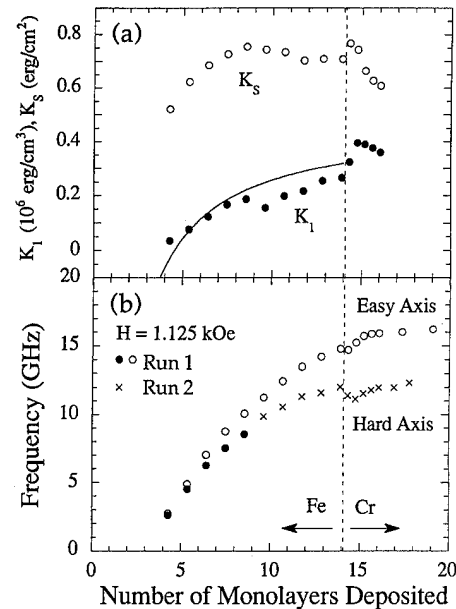

FIG. 2. (a) Values of the surface anisotropy constant K_s and the cubic anisotropy constant K_1 calculated from the data in (b) are shown. The solid curve is an empirical curve for K_1 from Ref. 1. (b) Easy and hard axis BLS frequencies measured in two experiments in which a 13.9 ML Fe film was capped with Cr are plotted. The frequency error bars are smaller than the symbols used.

axes, we may deduce the values of both K_1 and $(K_s^{(1)} + K_s^{(2)})/2$, the average surface anisotropy constant, henceforth referred to as K_s .

Experiments were performed to verify that surface contamination can be neglected in our studies. Repeated growth runs then showed that there was some scatter in the BLS frequencies measured at small Fe thicknesses, but that for larger thicknesses these frequencies were highly reproducible. No magnetic signal was ever observed with MOKE or BLS for Fe thicknesses less than about 3 ML. Even if the remanent magnetization was oriented normal to the film plane one would still expect to observe some signal in both the MOKE and BLS experiments as the applied field pulls the magnetization towards the film plane. Alternatively these films may not be ferromagnetic at room temperature. Since other researchers have observed ferromagnetism at room temperature even in 1 ML films,² we are presently performing a detailed structural analysis in order to determine whether our Fe films are continuous for thicknesses less than 3 ML.

In Fig. 2 we have combined data from two growth runs to form one data set from which we have calculated the values of K_1 and K_s as a function of the film thickness. We note that both the easy and hard axis frequencies show a small reduction with the initial deposition of Cr and that this is reflected in the small peak in K_s that is observed at this point. Interestingly the deposition of Cr seems to lead to a significant increase in the value of K_1 . However, for a Fe film that was ~ 15 ML thick, the thickness is uncertain because the Fe rate became unstable during the growth, the deposition of Cr was again found to produce a peak in the calculated value of K_s but no increase in the

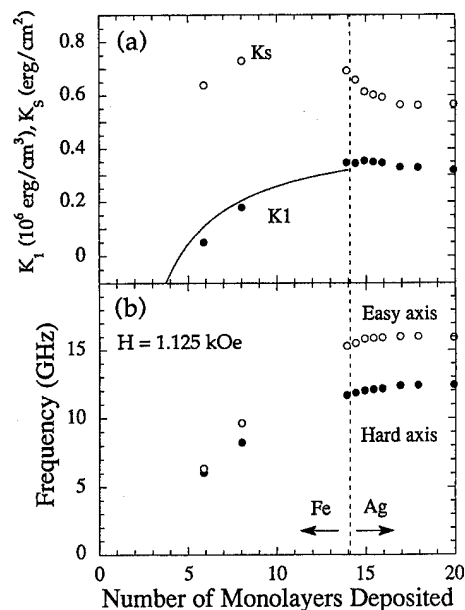

FIG. 3. (a) Values of the surface anisotropy constant K_s and the cubic anisotropy constant K_1 calculated from the data in (b) are shown. The solid curve is an empirical curve for K_1 derived in Ref. 1. (b) The easy and hard axis BLS frequencies measured in an experiment in which a 13.9 ML Fe film was capped with Ag are plotted. The frequency error bars are smaller than the symbols used.

value of K_1 was observed. Figure 3 shows the spin wave frequencies measured in a growth run for which Ag was deposited on to a 13.9 ML Fe film. The values of the calculated anisotropy constants are again shown. Comparing Figs. 2 and 3 we see that the effects of capping with Ag and Cr are qualitatively different since the spin wave frequency increases monotonically for the case of Ag but not for Cr.

We now compare the values obtained for K_1 and K_s with those obtained by other authors. The relationship $2K_1/M = (0.55 - 2.5/N)$ was previously found¹ to give a good fit to the value of the in-plane cubic anisotropy field (measured in kOe). We have plotted this curve in Figs. 2(b) and 3(b) and see that it is in reasonable agreement with our experimental data. We note that in Fig. 2(b) the small jump in the value of K_1 between 8 and 9 ML of Fe is probably an artefact since this is the point at which the two sets of hard axis BLS data have been pasted together. The apparent enhancement of the value of K_1 when Cr is deposited onto the 13.9 ML film is intriguing but further experiments are required in order to confirm this effect. From Fig. 3(b) we see that capping of the 13.9 ML film with Ag has little effect upon the value of K_1 which is in agreement with reports that the value of K_1 is insensitive to the material deposited at the upper interface.¹

From Figs. 2(b) and 3(b) we see that the value of K_s for an uncoated Fe film is approximately equal to 0.70 erg/cm^2 for Fe thicknesses greater than or equal to 6 ML, but that it appears to decrease for smaller Fe thicknesses, in qualitative agreement with previous studies.¹ From Fig. 3(b) we see that approximately 3 ML of Ag must be deposited before the value of K_s becomes saturated at about 0.56 erg/cm^2 . Further work is required to determine whether this gradual change in K_s results from the growth mode of the Ag, the effects of strain, or is purely an electronic effect. If we assume that the upper and lower Fe/Ag interfaces are identical in terms of their surface anisotropy constant, and this need not be the case,⁷ then we deduce surface anisotropy values of 0.56 erg/cm^2 for the Fe/Ag interface and 0.84 erg/cm^2 for the Fe/vacuum interface. These values are somewhat smaller than those of 0.81 and 0.96 erg/cm^2 reported in Ref. 1 for the Fe/Ag and Fe/vacuum interfaces, respectively. From Fig. 2(b) we see that, with the deposition of Cr, K_s increases to 0.77 erg/cm^2 before decreasing to 0.61 erg/cm^2 . This non-monotonic behavior of K_s corresponds to the small dip seen in both the hard and easy axis spin wave frequencies, which has been observed in all of our experiments. This may be associated with the antiferromagnetic ordering of successive layers of Cr moments, although detailed structural studies are required in order to determine the effects of interfacial roughness.

In conclusion, we have shown how *in situ* BLS may be used to quickly obtain information on the evolution of magnetic anisotropies during the growth of ultrathin ferromagnetic films. We have observed the development of the magnetic interface anisotropy during the deposition of submonolayer quantities of Ag and Cr onto 13.9 ML Fe films and have shown that Ag and Cr have a qualitatively different effect. We suggest that the Cr moment may be effective in determining the interface anisotropy constant at the Fe/Cr interface.

We would like to acknowledge the help of E. Gu and E. Ahmed in the preparation of the Ag single crystal substrate, and the financial support of the EPSRC and the DRA.

Magneto-optical investigation of the fcc–bcc phase transition of Fe wedges sandwiched between CuNi alloys (abstract)

H. Theuss,^{a)} D. Weller, and A. Carl^{b)}

IBM Almaden Research Center, 650 Harry Road, San Jose, California 95120-6099

We report a systematic investigation of the fcc–bcc structural phase transition of thin Fe films sandwiched between CuNi alloys. The structures were of the type substrate/20 nm Pt/10 nm CuNi/0–2 nm Fe wedge/1 nm CuNi/2 nm Pt. All films were deposited in high vacuum by electron beam evaporation at temperatures ranging from 400 °C (Pt seed layer) to 100 °C (CuNi alloy layers and Fe wedge) to 20 °C (Pt cap layer). The CuNi composition ratio was varied in 10 at. % steps in order to vary its lattice constant from $a=0.3607$ nm (Cu) to 0.3517 (Ni) nm, which encompasses the value of gamma Fe (fcc low spin state). X-ray diffraction measurements reveal strong (111) texturing with an alignment of the Pt $\langle 111 \rangle$ axis better than 5 deg (rocking curve width) of the completed structures. Kerr loops in fields ± 18 kOe were recorded as function of the Fe-wedge position with a spatial resolution of about 0.8 mm, corresponding to 0.1 nm Fe thickness resolution. These hysteresis loops reveal the saturation Kerr angle (0.1 mdeg resolution), the saturation field (anisotropy field) and a paramagnetic slope, which are all analyzed as function of the Fe thickness and the CuNi composition. Clear evidence for the formation of paramagnetic Fe is found for Cu-rich CuNi alloys, where a Kerr rotation below the resolution limit of our apparatus extends up to >2 nm Fe thickness. The transition thickness from fcc to bcc Fe, as characterized by the onset of a linear uptake of the Kerr rotation, shows a pronounced maximum near about 25 at. % Ni, indicating that a small compression of the Fe lattice constant (about -2%) leads to the nonferromagnetic fcc Fe state. A similar study, using CuAu alloys with the aim of characterizing the high spin ferromagnetic fcc Fe phase, is in progress.¹ © 1996 American Institute of Physics. [S0021-8979(96)68008-0]

Dependence of structural and magnetic properties on deposition angle in electron-beam evaporated Co/Pt multilayer thin films

Ki-Seok Moon and Sung-Chul Shin

Department of Physics, Korea Advanced Institute of Science and Technology, Kusung-Don, Yusung-Gu, Taejeon 305-701, Korea

The effects of deposition angle on the structural and magnetic properties of e-beam evaporated Co/Pt multilayer thin films prepared on tilted substrates were examined. It was found that the [111] crystallographic orientations of the multilayer thin films were not aligned with columnar growth orientations and that they remained normal to the substrate planes, irrespective of deposition angle, even though the deposition angle was severely oblique up to 60° . Interestingly enough, the magnetic easy axis orientation was nearly aligned with the substrate normal, irrespective of deposition angle, which suggested that surface anisotropy was a major reason for the perpendicular anisotropy in Co/Pt multilayer thin films. © 1996 American Institute of Physics. [S0021-8979(96)72108-7]

I. INTRODUCTION

Co-based multilayer thin films have been the subject of considerable investigation because of their novel properties and potential technological applications. In particular, the application of these materials to magneto-optic (MO) recording is of great interest today due to superior environmental stability and a larger Kerr effect at short wavelength (<500 nm) compared to the current choice for MO media—rare-earth-transition metal (RE-TM) alloy thin films.¹ In particular, Co/Pt multilayer thin films have been reported as the best choice owing to a large spin-orbit coupling.²

The magnetic properties of Co/Pt multilayer thin films were reported to be very sensitive to preparation methods and condition, as well as to sublayer and total film thicknesses: sputtering gas³ and pressure⁴ in sputtering, and vacuum pressure and substrate temperature in evaporation.⁵ In this article, we report the effects of deposition angle on the structural and magnetic properties of Co/Pt multilayer thin films.

II. EXPERIMENT

Co/Pt multilayer thin films were prepared on glass substrates by e-beam evaporation in a vacuum system maintained at about 6×10^{-6} Torr. To achieve oblique deposition, the substrates were mounted on tilted substrate holders making the angle of incident vapor beam 0° , 15° , 30° , 45° , and 60° with respect to each substrate normal. The multilayer structure was achieved by alternatively exposing the substrate to two sources via a rotating substrate holder. The substrate holder was placed 25 cm above the sources. The dwelling time spent by the substrate above each source could be controlled by a computer interfaced to a stepping motor which drove the substrate holder. Two sources were physically separated by stainless-steel shields to prevent the cross contamination of their fluxes. The sources were screened with a shutter driven by a stepping motor in order to prevent deposition to the substrates during rotation of the substrate holder. Typical deposition rates of 0.28 Å/s for Co and 0.25 Å/s for Pt, monitored by two corresponding quartz crystal sensors, were kept constant within a 10% fluctuation to achieve the same modulation wavelength in all samples. All

samples were designed to have the same total thickness of 300 Å, consisting of a 4 -Å-thick Co and 9.2 -Å-thick Pt sublayer. Since a series of samples with different angles of incidence was prepared in the same run under identical conditions, possible variations of preparation conditions between different runs were eliminated.

The film structure was examined by low- and high-angle x-ray diffractometry and the growth morphology of the film was investigated by microfractography. A preferred orientation and degree of texture of the film was studied from the measurements of a rocking curve and pole figure. Magnetization was investigated using a vibrating-sample magnetometer. The magnetic anisotropy was determined from analysis of a torque curve measurement of an applied field of 10 kOe.

III. RESULTS AND DISCUSSION

All samples in this study developed low-angle x-ray diffraction peaks irrespective of the deposition angle, which suggests the existence of a multilayer structure in those samples. High-angle x-ray diffraction experiments revealed that the films were polycrystalline grown along the [111] crystallographic orientation having a d_{111} spacing of 2.201 Å.

Figure 1 shows the typical cross sections of the samples examined by a scanning electron microscope in order to examine the growth morphology depending on the angle of incidence. A columnar structure was observed for all samples. This columnar microstructure has been commonly observed for deposited atoms having low mobility.⁶ In the initial stages of film formation a random distribution of small crystallites is created on the substrate and each crystallite acts as a nucleus for further growth. The region of the substrate behind a growing crystallite is prevented from receiving metal vapor because this region is in the shadow of the crystallite. When the rate of migration of atoms in the deposited regions to the shadowed ones is smaller than the rate of void formation via shadowing, column formation occurs during deposition. Therefore, the void region becomes larger and the columns become more tilted with an increasing angle of incidence. The relation between the columnar growth orientation β and the angle of incidence α is plotted for Co/Pt

FIG. 1. Cross-sectional scanning electron micrographs of (4 Å Co/9.2 Å Pt)₁₅₂ prepared at the incidence angles $\alpha=0^\circ$ and $\alpha=60^\circ$.

multilayer thin films in Fig. 2. One can see that Co/Pt multilayer thin films generally follow the tangential rule, $\tan \alpha = 2 \tan \beta$.⁸

Interestingly enough, the [111] growth orientation remains normal to the substrate plane even for the samples fabricated at large α 's. Figure 3 shows x-ray rocking curves along the substrate normal for (4 Å Co/9.2 Å Pt)₁₅₂ with various α 's. As seen in Fig. 3, the peak becomes smaller and the full width at half-maximum widens with increasing α . But the peak position does not nearly change with α . Thus, one would imagine that the [111] growth orientation remains nearly aligned with the substrate normal, irrespective of deposition angle. This fact was also confirmed by examining x-ray pole figures. Figure 4 shows a typical [111] pole figure for the sample prepared at $\alpha=45^\circ$. The center of the plot and

FIG. 2. Columnar growth orientation, β , vs the angle of incident vapor beam, α , in Co/Pt multilayer thin films. Here, α and β are measured from the substrate normal.

FIG. 3. X-ray rocking curves along a fcc [111] texture for (4 Å Co/9.2 Å Pt)₁₅₂ with various α 's.

the cross indicate the substrate normal and the direction of the incident vapor beam, respectively. The pole density is expressed by numerical values in the given regions and has been normalized by the average value. One can clearly see that the [111] direction lies almost along the direction of the substrate normal. A similar result was observed for the sample prepared at $\alpha=60^\circ$. Therefore, it may be concluded that the [111] crystallographic orientation is not aligned with columnar growth orientation in evaporated Co/Pt multilayer thin films.

FIG. 4. The [111] pole figure of (4 Å Co/9.2 Å Pt)₁₅₂ prepared at deposition angle $\alpha=45^\circ$.

FIG. 5. Variation of the torque curve with the incidence angle of (4 Å Co/9.2 Å Pt)₂₃.

We also measured the dependence of the saturation magnetization M_s per Co volume on α . The M_s of the film at $\alpha=0^\circ$ is 1260 emu/cc (87.5% of a Co bulk magnetization) and there is a monotonic decrease with increasing α . The result is believed to probably be caused by an increase of the porous region due to the enhancement of the shadowing effect for a higher α .

Figure 5 shows the variation of the torque curve with varying α 's. As noted in Fig. 5, the specific torque τ_p becomes smaller and ϕ_0 , the angle where the torque is zero in the first quadrant of ϕ , becomes larger. To estimate the intrinsic anisotropy energy and the easy axis orientation, torque curves were analyzed by a simple model described as follows.⁷ We assume that a film has a uniaxial anisotropy with a single easy axis making an angle δ from the substrate normal. We consider only the first-order anisotropy energy constant K_u and ignore any higher order terms. Then

$$K_u^2 = K_s^2 + \tau_p^2 + 2K_s\tau_p \cos(2\phi_0), \quad (1)$$

$$\delta = \phi_0 - (1/2) \tan^{-1} \left(\frac{K_s \sin(2\phi_0)}{K_2 \cos(2\phi_0) + \tau_p} \right), \quad (2)$$

where K_s is the shape anisotropy energy of $2\pi M_s^2$ and M_u is the first-order anisotropy energy constant.

In Table I, we summarize the calculated results according to Eqs. (1) and (2). A monotonic decrease of K_u with increasing α is believed to be closely correlated with the structural change of the sample. The K_u associated with an interface is phenomenologically described as $K_u = 2K_{\text{int}}/t_{\text{Co}} + K_v$, where K_{int} is the surface anisotropy originating from the interface per unit area. t_{Co} is the Co thickness, and K_v is the volume anisotropy consisting of the shape anisotropy, magnetocrystalline anisotropy, and magnetoelastic anisotropy. Since the texture and interface of a film become poor with increasing α , the magnetocrystalline and the surface anisotropies are expected to decrease with α . The shape anisotropy is also decreased with α due to a smaller M_s for a higher α . In Table I, it is very interesting to note that the easy

TABLE I. Magnetic parameters of (4 Å Co/9.2 Å Pt)₂₃ prepared at oblique incidence. Here, τ_p is the specific torque, ϕ_0 is the angle where the torque is zero in the first quadrant of ϕ , K_s is $2\pi M_s^2$, K_u is the first-order anisotropy energy constant, and δ is the easy axis orientation measured from the substrate normal.

α (deg)	τ_p (10^6 dyn cm/cm ³)	ϕ_0 (deg)	K_s (10^6 ergs/cm ³)	K_u (10^6 ergs/cm ³)	δ (deg)
0	1.7	0.0	9.8	11.5	0.0±0.1
15	1.5	8.2	9.7	11.2	1.1±0.1
30	1.2	20.0	7.7	8.8	2.6±0.3
45	1.2	41.5	6.5	6.8	5.1±0.5
60	0.7	45.0	4.0	4.0	4.9±0.6

axis orientation remains nearly normal even for the sample prepared at $\alpha=60^\circ$. This is in sharp contrast in comparison to ferromagnetic single-layer films.⁸ In those systems, the easy axis orientation was reported to be dependent on the direction of the incident vapor beam and thus, the growth-induced anisotropy of the columnar structures was believed to be a major source of the magnetic anisotropy. However, the fact that the easy axis orientation is insensitive to columnar growth orientation in Co/Pt multilayer thin films implicitly implies the importance of the surface anisotropy in this system.

IV. CONCLUSIONS

We have studied the effects of deposition angle on the structural and magnetic properties of e-beam evaporated Co/Pt multilayer thin films on the tilted substrates. The [111] crystallographic orientation of samples was not aligned with the columnar growth orientation and remained normal to the substrate planes, in spite of increasing deposition angle. Also, it was found from the torque curve that the magnetic easy axis orientation was nearly aligned with the substrate normal, irrespective of deposition angle.

Simulations of inhomogeneous magnetization processes in ultrathin films with growth-induced roughness (abstract)

A. Moschel and A. Zangwill

School of Physics, Georgia Institute of Technology, Atlanta, Georgia 30332

M. D. Stiles

Electron Physics Group, National Institute of Standards and Technology, Gaithersburg, Maryland 20899

Magnetization in ultrathin films depends in a very sensitive way on the morphology of the surface of the films. Using a X - Y model with enhanced anisotropy at the step edges, we have calculated hysteresis loops in different directions at zero temperature for nominally vicinal and flat films with growth-induced surface roughness. For the vicinal films the influence of the width of the terraces and the strength of the anisotropy at the edges is studied. For the "flat" films the influence of the shape and the size of 2D and 3D island roughness is investigated. Some interesting properties of the coercive field and the remanent magnetization are discussed and compared to some experimental results. © 1996 American Institute of Physics. Measurement of the crystalline anisotropy in sputtered single-crystal FeTaN thin films

L. Varga and W. D. Doyle

Department of Physics and Astronomy and Center for Materials for Information Technology, The University of Alabama, Tuscaloosa, Alabama 35487-0209

FeTaN single-crystal thin films were grown in order to investigate the dependence of the crystalline anisotropy constant, K_1 , on the Ta and nitrogen content. Films with 5 and 10 wt % Ta and different nitrogen contents were prepared by dc sputtering on MgO(100) substrates at elevated temperatures. The film/substrate orientation was (100)∥(100) and [100]∥[110]. The values of K_1 were determined by measuring the in-plane angular dependence of the ferromagnetic resonance spectra and agreed very well with the values obtained from torque measurements, indicating that the total volume was biaxial cubic material. The hysteresis loops were characteristic of biaxial anisotropy and the anisotropy fields estimated from magnetization curves were consistent with the resonance and torque data. In Fe, K_1 was $(4.8 \pm 0.1) \times 10^5$ ergs/cc in good agreement with the bulk value. In FeTa, K_1 decreased to $(4.4 \pm 0.1) \times 10^5$ and $(3.5 \pm 0.1) \times 10^5$ ergs/cc for 5 and 10 wt % Ta content, respectively, and further to $(2.7 \pm 0.1) \times 10^5$ and $(2.1 \pm 0.1) \times 10^5$ ergs/cc in $(\text{Fe}_{95}\text{Ta}_5)\text{N}$ depending on the nitrogen content. The nitrogen addition to $\text{Fe}_{90}\text{Ta}_{10}$ resulted in the formation of epitaxial $(\text{FeTa})_4\text{N}$ which is an fcc structure with a negative K_1 of $(-1.5 \pm 0.2) \times 10^5$ ergs/cc. © 1996 American Institute of Physics. [S0021-8979(96)08408-4]

I. INTRODUCTION

The optimization of the soft magnetic properties of FeXN high magnetization alloys for recording head applications will require the knowledge of the crystalline anisotropy K_1 , and the magnetostriction which impact the ripple structure.^{1,2} The crystalline anisotropy of FeXN alloys has been assumed to be the same as bulk Fe,^{2,3} based on the magnetic properties of Fe_{16}N_2 ,⁴ and their soft properties were widely believed to originate only from their nanocrystalline structure.^{2,3} In this work we report the direct measurement of K_1 in single-crystal Fe, FeTa, and FeTaN films.

II. EXPERIMENTAL METHOD

MgO single-crystal platelets with (100) orientation were chosen as the substrate material for epitaxial growth based on earlier work^{5,6} which found the film/substrate orientation to be $\text{Fe}(100)\parallel\text{MgO}(100)$ and $\text{Fe}[100]\parallel\text{MgO}[110]$ with a lattice mismatch of -3.8% . FeTaN films of different Ta and nitrogen content were sputtered from hot pressed Fe, $\text{Fe}_{95}\text{Ta}_5$, and $\text{Fe}_{90}\text{Ta}_{10}$ targets at a total argon-nitrogen pressure of 4 mTorr, and fixed sputtering power of 50 W onto commercially obtained, epitaxially polished substrates at temperatures of 150–200 °C. The nitrogen content was varied by controlling the flow rate of the N_2 gas during deposition. The deposition rates were 1–2 Å/s and the film thickness ranged from 800 to 2000 Å.

After preparation, film thicknesses were determined by a Dektak Profilometer and used to calculate the volume of the samples measured in the magnetometer and torque meter. The structural analysis was carried out on a Rigaku D/Max-2BX thin-film diffractometer with $\text{Cu } K_\alpha$ radiation. Diffraction

patterns in the $2\theta-\theta$ and 2θ modes were used to determine the structure, the lattice parameter, and the orientation of the films with respect to the substrate.

The values of K_1 were obtained by measuring the angular dependence of the ferromagnetic resonance (FMR) using a spectrometer with a 34.48 GHz cylindrical TE_{011} -mode resonant cavity. A static field, up to 18 kOe, was rotated in the plane of the film. From the fit to the theoretical model^{6,7} the saturation magnetization M_s , and K_1 were determined. The torque was recorded as a function of angle and applied field up to 10 kOe in the plane of the films. The maximum torque above the anisotropy fields and the total volume of the sample were used to calculate the anisotropy constant in sup-

port of the FMR data. The hysteresis loops were measured along [100], [110], [010], and $[\bar{1}\bar{1}0]$ directions of the substrate. The anisotropy field $H_K = 2K_1/M_S$ was estimated from the saturation field in the hard direction.⁸

III. RESULTS AND DISCUSSION

The x-ray diffraction patterns (Fig. 1) in the $2\theta-\theta$ mode for Fe, FeTa, and FeTa_N showed only a strong (200) peak consistent with the expected growth orientation of Fe(100)||MgO(100). No evidence of a randomly oriented polycrystalline component was observed although if a small intensity (110) diffraction peak were present, it would be hidden under the right shoulder of the MgO(200) diffraction peak at $\sim 44.5^\circ$. The (200) peaks of FeTa and FeTa_N [Figs. 1(b), 1(c)] were shifted toward smaller angles relative to the Fe(200) peak consistent with the expected lattice expansion of the α -Fe. The lattice parameters were determined from the d spacing of the (200) planes (Table I). The calculated nitrogen content⁹ for the two (Fe₉₅Ta₅)N samples were 2.9 and 8.6 at %. The linewidth of the (200) film peak increased and its intensity decreased relative to the MgO(200) peak with the addition of Ta and nitrogen, suggesting a decrease in the degree of crystallinity or an increase in nonuniform strain. To collect information about the orientation relationship of the substrate and the film, the 2θ mode was used. When the sample was aligned such that the low angle incident beam, the normal of the film and the [100] direction of MgO were in the same plane, a diffraction peak corresponding to the (112) planes of the film appeared on the spectra [Figs. 2(a), and 2(b)] which disappeared with a slight rotation in the plane ($<5^\circ$). This again is consistent with the expected orientation of $[110]||[100]$. For the FeTa and FeTa_N compared to Fe, a low intensity peak [Fig. 2(b)], whose amplitude did not change with rotation, was observed at an angle consistent

FIG. 2. X-ray spectra of (a) Fe and (b) FeTa films in the 2θ mode.

FIG. 3. Ferromagnetic resonance lines for (a) two different Fe and (b) FeTa and FeTa_N sputtered films.

with a reflection from the (110) planes. This suggests that some amount of polycrystalline material with a (200) texture is also present.

When the nitrogen flow rate was increased to 0.7 sccm for the Fe₉₀Ta₁₀ target from the maximum of 0.3 sccm used for Fe₉₅Ta₅, the phase structure completely changed from bcc α -Fe to fcc (FeTa)₄N [Fig. 1(d)].

The FMR spectra for several films are shown in Fig. 3. The narrowest line occurred in the Fe films and varied from 90 to 140 Oe [Fig. 3(a)], which is in the range reported by others (50–400 Oe).^{5,10} It increased to ~ 500 Oe in FeTa and ~ 1000 Oe in FeTa_N [Fig. 3(b)], consistent with the decrease in degree of crystallinity suggested by the increased x-ray linewidth. Also, in some of the resonance spectra, extra resonance lines were observed [Fig. 3(a)] close to the main (i.e., highest amplitude) line, possessing the same biaxial symmetry (Fig. 4), with essentially the same value of K_1 but a slightly smaller ($\sim 5\%$) value of M_S . This is not consistent with a surface oxide layer which would be expected to have a much lower value of M_S . At the present time the extra resonance cannot be explained.

The angular dependence of the main resonance in the plane (Fig. 5) could be fitted very well with a simple biaxial anisotropy in all cases. For the α -phase films K_1 was positive; i.e., the easy axis was along the [100]. The values of K_1 and M_S obtained from the fit are listed in Table I. For Fe, the results are in good agreement with the bulk values.⁶ Both K_1 and M_S decreased in the FeTa and further in FeTa_N. The magnetization values for all the α -phase films were in good agreement with those obtained from the vibrating sample magnetometer (VSM) measurement and values reported for polycrystalline films,⁹ showing that the magnetization is rela-

FIG. 4. Ferromagnetic resonance spectra of Fe in the film plane. The directions denote approximately the film directions and the applied field was changed by 10° steps.

FIG. 5. Angular dependence of the ferromagnetic resonance field in the (100) plane of Fe (○), FeTa (◇), FeTaN (△), and (FeTa)₄N (×). The angle is measured with respect to the [110] direction of the substrate.

tively constant throughout the films. In the (FeTa)₄N, K_1 changed sign and decreased in absolute magnitude, consistent with the expectation for fcc Fe₄N. The magnetization obtained from the VSM for (FeTa)₄N was ~15% less than the FMR value which means that a significant fraction of the film was not contributing to the biaxial resonance. This could be a polycrystalline, lower moment nitride phase, which did not appear in the x-ray spectra.

The angular dependence of the torque in the (100) plane (Fig. 6) showed a pure biaxial behavior and crystal symmetry in agreement with the FMR measurements. The torque curves below the anisotropy field [Fig. 6(a)] fit a simple biaxial, Kondorsky-type switching.^{11,12} At fields higher than the anisotropy field [Fig. 6(b)], the maximum torque in the (100) plane was independent of field, characteristic of a uniform anisotropy. The values of the anisotropy calculated from the maximum torque and the total volume of the

FIG. 6. Torque curves (a) below and (b) above the anisotropy field for Fe, FeTa, FeTaN, and (FeTa)₄N in the film plane.

FIG. 7. Magnetization curves for (a) Fe, (b) FeTa, (c) FeTaN, and (d) (FeTa)₄N sputtered films along [100] and [110] directions of the films.

samples were in very good agreement with the FMR data for Fe, FeTa, and FeTaN (Table I), again confirming that the films were well oriented, single phase, single crystals.

The M - H loops also showed biaxial symmetry in the plane in all cases (Fig. 7), in agreement with FMR and torque data. The addition of Ta and nitrogen caused an increase in the coercivity implying a decrease in the homogeneity of the films, consistent with the x-ray and FMR data. The value of K_1 extracted from M_S and H_K confirmed the FMR and torque results (Table I).

IV. CONCLUSION

The crystalline anisotropy of Fe is reduced by the addition of Ta and nitrogen. FeTa films with 10 wt % Ta have smaller K_1 than samples with 5 wt % Ta. The value of K_1 in α -phase (Fe₉₅Ta₅)N single-crystal films was found to be $\sim 2\text{--}3 \times 10^5$ erg/cc, roughly half the value in pure Fe. This alone is not sufficient to explain the soft properties of FeTaN, and so the answer must be related to the magnetostriction and the nanocrystalline structure of these materials. In fcc-phase (FeTa)₄N single-crystal films, K_1 changed sign and decreased to -1.5×10^5 ergs/cc. This suggests the possibility of further optimizing the soft properties of FeTaN for recording head applications by preparing a mixed phase polycrystalline system with zero effective crystalline anisotropy.

Magnetic properties and crystal structure of FeTaAlN soft magnetic materials for MIG head (abstract)

Yiqun Li, Bingchu Cai, Xianglin Zeng, and Dong Xu

Information Storage Research Center, Shanghai Jiao Tong University, Shanghai 200030, People's Republic of China

Fe-based nitride films have been expected as promising head core materials used for high-density magnetic recording MIG head due to their large saturation flux density combined with excellent soft magnetic properties. Recent studies found that the addition of 8–13 at. % Ta in Fe–N resulted in a remarkable improvement of thermal stability.¹ It was also reported that small amount of Al appeared to inhibit the formation of γ' -Fe₄N phase and to prevent the grain growth during annealing.² In this paper, the magnetic properties and crystal structure of a new Fe–M–N soft magnetic film, FeTaAlN, has been reported. FeTaAlN films about 3 μm thick were prepared on glass substrate by dc magnetron sputtering method in Ar+N₂ plasma and then annealed in vacuum. The films generally present high $4\pi M_s$ (15–20 kG). X-ray diffraction results show that both as-deposited and annealed films have only two phases, an α -Fe phase with preferred (110) axis orientation and a Ta₃N₅ phase. Annealing is essential in lowering H_c without seriously diminishing $4\pi M_s$ of the films; the film with the lowest H_c (about 0.5 Oe) has a $4\pi M_s$ of above 15 kG. The peak broadenings of both the α -Fe phase and the Ta₃N₅ phase are observed as annealing temperature increases. Meanwhile, the (110) peaks of α -Fe shift slightly to higher 2θ value. This indicates that the interstitial nitrogen atoms come out of α -Fe lattice when the films are annealed and a part of b.c.t. α -Fe is transferred into b.c.c. α -Fe, which causes the broadening of α -Fe peak. On the other hand, the segregated nitrogen atoms may react with Ta atoms that dissolved substitutionally in α -Fe to form fine Ta₃N₅ particles and make the Ta₃N₅ peak broadened. Thus, it is thought that the decrease of H_c is mainly due to the reduction of internal stress. The magnetostrictions of the films are on the order of 10^{-6} . FeTaAlN film presents high saturation flux density and good soft magnetic properties even after annealing at 500 °C, and it is potentially a superior substitute for the core materials of high-density recording MIG head. © 1996 American Institute of Physics. Magnetic domain control of thick Fe-M(Zr,Ta)-N films for digital VCR metal in gap heads

M. Uchizawa, J. Fujita, H. Kobayashi, and S. Tanabe

Advanced Technology R&D Center, Mitsubishi Electric Corporation, 8-1-1 Tsukaguchi-Honmachi, Amagasaki, Hyogo 661, Japan

Magnetic domain structures of thick and small area ($45 \times 45 \times 5 \mu\text{m}^3$) Fe-M(Zr or Ta)-N films were observed by a scanning Kerr-effect microscope (SKEM). The important factors in controlling the magnetic domains are the magnetostriction and the uniaxial anisotropy. By changing the N content in bcc Fe and the Ar pressure during sputtering, the saturation magnetostriction constant λ_s and the anisotropy field H_k were controlled in the range of 3×10^{-6} – 6×10^{-6} and 10–130 A/m, respectively. Clear and consecutive changes in the domain structures were observed by varying the film's λ_s , H_k , and stress σ , and the observed structures agree qualitatively with the structures predicted by theoretical calculations. The wall structure where Bloch-like rotations and the Neel-like rotations are combined was observed by SKEM. The metal in gap heads using different λ_s and H_k films were fabricated and the output at 20 MHz was measured. A lower H_k is not necessarily better for obtaining a higher output in high-frequency ranges. The head output depends on the film's magnetic domain structure, and the structure can be controlled by changing the λ_s and H_k . © 1996 American Institute of Physics. [S0021-8979(96)08508-0]

I. INTRODUCTION

About $10 \mu\text{m}$ or less track width and the same order gap depth are required for digital VCR metal in gap (MIG) heads.¹ The metal films at both sides of the gap must be thick in order to obtain sufficient recording properties.² The aspect ratio of the track width to the film thickness is 3:1 to 2:1. In order to obtain higher output in high-frequency ranges, the permeability in the direction of the film thickness and the magnetic domain structure are important.³ The magnetic domain structures of these kind of thick "film" are completely different from the domain structures of wide area films and typical thin films. Wide area Fe-Zr-N film domain structures have been reported and the film has a clear domain structure even for isotropic films as compared to Sendust (FeSiAl) film domain structures.⁴ However, small size thick Fe-Zr-N film domain structures have not been reported. The magnetic domain structure was observed using small scale samples, $45 \times 45 \times 5 \mu\text{m}^3$ by scanning Kerr-effect microscope (SKEM) in this work. The important factors in controlling the magnetic domains of this shape of Fe-M(Zr or Ta)-N film are the saturation magnetostriction constant λ_s and anisotropy field H_k . The relation between those parameters and the domain structures was observed by SKEM, and the observed structures were compared with the structures predicted by theoretical calculations considering each energy term (exchange, anisotropy, magnetoelastic, and magnetostatic energy). The magnetostatic energy for each shape and each magnetization distribution was calculated using a three-dimensional finite element method (3D-FEM). Furthermore, a wall structure where Bloch-like rotations and surface Neel-like rotations are combined was observed. This domain structure was predicted theoretically⁵ but had not been observed in a real soft magnetic film. Finally, MIG heads using different λ_s and H_k films were fabricated and the outputs at 20 MHz were compared.

II. EXPERIMENTAL METHODS

The S-polarized longitudinal mode of the SKEM (Phase Metrics) was used in the observation. As shown in Fig. 1(a),

a 200 kHz sinusoidal field is applied to the sample in the transverse direction. A polarized argon laser beam is injected at an oblique angle, and the magnetization variation synchronized at 200 kHz in longitudinal and perpendicular directions is picked up by a lock-in amplifier. The selected signal magnitude and phase are graphically represented. The lines in an image do not show the walls themselves but show the movement of the walls. Two opposite phase 90° walls' movement appears as in Fig. 1(b). That is, when the applied magnetic field in the direction from left to right is increased, the shaded part of the magnetization in the longitudinal direction is increased and the hatch part magnetization is decreased. This magnetization magnitude and phase information is pictured as white and black lines along the walls.

The samples were prepared using an ion beam sputtering (IBS) deposition method on CaTiO_3 or nonmagnetic ferrite

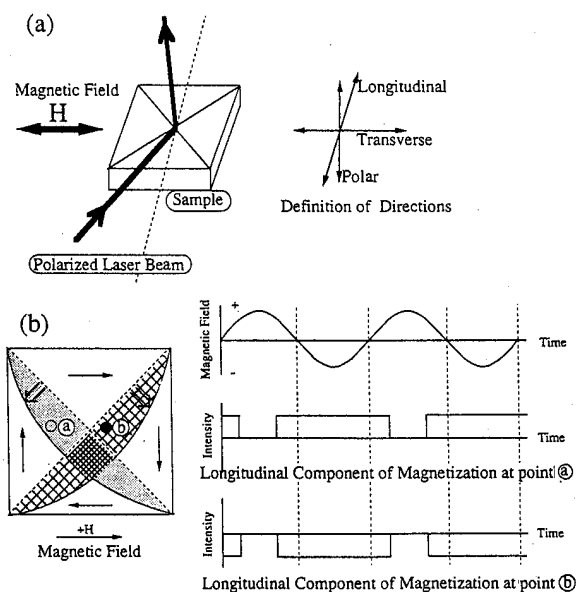

FIG. 1. (a) Principle of the SKEM observation and definition of the directions. (b) Explanation of why white and black lines appear along walls.

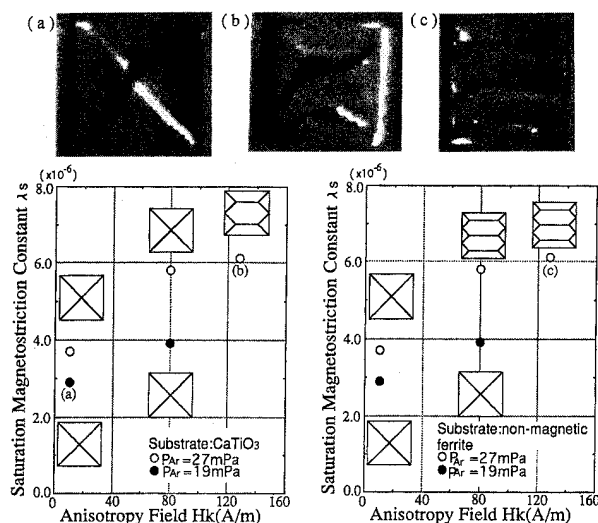

FIG. 2. Variation of the magnetic domain structures for different λ_s and H_k samples on CaTiO_3 substrates.

substrates. An $\text{Fe}_{90}\text{Zr}_{10}$ target was used and N_2 gas flowed across the substrate. The as-deposited Fe-Zr-N amorphous films were annealed at 530 °C without applying a magnetic field in order to obtain fine crystalline Fe-Zr-N films. Some films were annealed again at 250 °C in a 6400 A/m applied field in order to induce uniaxial anisotropy. By changing the N_2 pressure during deposition, the λ_s and H_k were controlled in the range of 3×10^{-6} – 6×10^{-6} and 10–130 A/m, respectively. The deposited and annealed 5- μm -thick samples were machined into a $45 \times 45 \times 5 \mu\text{m}^3$ plate.

III. RESULTS AND DISCUSSION

Figure 2 shows the variation of the magnetic domain structures for different λ_s and H_k film samples on CaTiO_3 and nonmagnetic ferrite. The thermal linear expansion coefficients α of CaTiO_3 and nonmagnetic ferrite are 115×10^{-7} and 85×10^{-7} (1/K), respectively. The α of the annealed Fe-Zr-N film is close to that of CaTiO_3 . That is, a larger tension is applied to the film in-plane directions on nonmagnetic ferrite substrate and the magnetization is easy to direct in-plane because λ_s is positive. The magnetic domains are separated by 90° walls in the case of a small λ_s and H_k film. As λ_s and H_k increase, 180° walls appear. 180° walls appear at a smaller H_k in the films on nonmagnetic ferrite because of the stronger in-plane tension. When a magnetic ferrite was

FIG. 3. Total energy of each domain structure for a $45 \times 45 \times 5 \mu\text{m}^3$ sample. When uniaxial anisotropy increases over a threshold value (a) shape changes to (b) shape. (c), (d) shape energies are large because of the large magneto-static energy. However, when the films are deposited on magnetic substrates, the energy decreases drastically even without closure domains.

FIG. 4. Calculated wall energy density vs wall width.

used as a substrate as in an MIG head, the domain structure could not be observed. We assumed that the magnetic ferrite substrate reduced the magneto-static energy on the boundary when the magnetization was directed perpendicularly. Therefore, the magnetization dispersion including the perpendicular direction is increased, and this increase of the dispersion makes the domain structures unclear.

Figure 3 shows the total energy (exchange, anisotropy, and magnetostatic) for each domain structure. The total wall energy was estimated using a well-known simple elliptic cylinder model. This model was explained briefly in LaBonte's paper.⁵ In his model, the wall energy density E_w is expressed as follows:

$$E_w = \frac{a}{2} K_u + \frac{1}{a} \pi^2 A + \frac{1}{4\mu_0} \frac{a^2}{a+D} M_s^2, \quad (1)$$

where a , K_u , A , μ_0 , M_s , and D represent the wall width, anisotropy energy density, exchange stiffness constant, permeability for free space, saturation magnetization, and thickness, respectively. We used the following values for Fe-Zr-N films:

$$K_u = 64 (\text{J/m}^3) (H_k = 80 \text{ A/m}), \quad A = 1.49 \times 10^{-11} (\text{J/m})$$

$$\times (\text{the value for Fe}),$$

$$M_s = 1.6 (\text{T}), \quad D = 5 \times 10^{-6} (\text{m}).$$

Figure 4 shows the calculated wall energy density E_w versus wall width. The minimum value is about 3.9×10^{-3} (J/m²) at about 60 nm wall width. The energy density for 90° walls is assumed to be 1/2 of that for 180° walls. The magnetostatic energies for (c)–(f) structures were calculated by 3D-FEM. The $45 \times 45 \times 5 \mu\text{m}^3$ magnetic film was divided into about 5000 finite elements, and the demagnetizing field H_d at each element which is magnetized in one direction was calculated. The magnetostatic energy E_m , of the whole film is obtained as follows:

$$E_m = \sum_i^i M_s H_d V_i, \quad (2)$$

where V_i is the volume of each finite element. If the films are deposited on a magnetic ferrite substrate, the total energy is lowered without producing well-defined domains and closure domains.

In the above simple calculations for the wall energy, the threshold value of H_k for moving from (a) to (b) in Fig. 3, which is the value obtained from the calculation, (the energy of a) = (the energy of b), is about 350 (A/m) (4.4 Oe) although

FIG. 5. Domain and wall movements for a rectangular shape ($35 \times 65 \times 5 \mu\text{m}^3$) film. (a) Observed in Longitudinal mode. 180° walls separate in white and black portions. (b) Observed in polar mode. 180° walls appear in monotone.

the threshold is about $130 \text{ (A/m)} (1.6 \text{ Oe}) H_k$ in real films as shown in Fig. 2. We thought that the reason for this quantitative disagreement between the calculated value and the observed value is in the model for the calculation of wall energy density. As LaBonte pointed out in his paper,⁵ the reversal must be more nearly like Neel walls on the top and bottom surfaces in order to decrease the magnetostatic energy. According to his paper, the wall energy density for a film thicker than 200 nm is less than 1/3 of that calculated from the simple elliptical cylinder model.

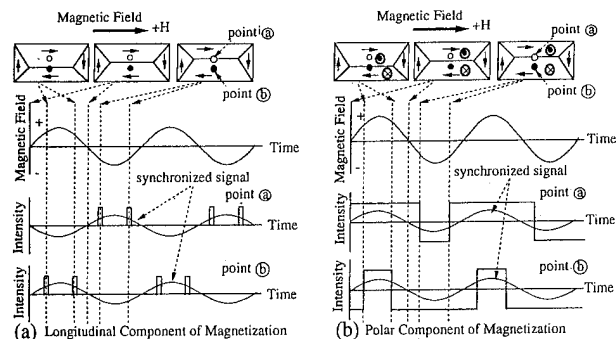

FIG. 6. Explanations for Fig. 4 photos. (a) The movement of longitudinal magnetization with applied field is in-phase in the upper half and out of phase in lower half. (b) The movement of polar magnetization is in-phase with the applied field.

Figure 5 shows the domain (wall) movement for a rectangular plate film ($35 \times 65 \times 5 \mu\text{m}^3$) observed by polar mode and longitudinal mode. In the photo taken in the longitudinal mode (a), the phases of the field and the magnetization are the same in the upper half and opposite in the lower half. However, in the photo taken in the polar mode (b), the boundary of the domains along the 180° wall appears as a monotone line which means the field and magnetization phases are the same at all times. In order to explain these results, we conclude the following:

(1) On the top surface, the magnetization in a wall has a longitudinal component and no perpendicular component, that is, the reversal is similar to a Neel wall. Therefore, the movement of the magnetization in the longitudinal direction is in-phase with the field variation in the upper half and out-of-phase in the lower half as shown in Fig. 6(a). This is the reason that white and black parts appear in a line in the longitudinal mode.

(2) The domains have a small perpendicular component as shown in Fig. 6(b), therefore, the movement of the magnetization in the polar direction is in-phase with the field variation throughout the whole region. This is the reason that the line is monotone in polar mode.

In order to confirm the relationship between the domain structure and the output level of a MIG head, we fabricated MIG heads using different H_k films around the gap. The permeability in the thickness direction of the film is important in obtaining higher output from an MIG head. In order to obtain high permeability in the thickness direction at high frequency, the magnetization process should be rotational and the magnetization of the film must be in-plane. Therefore, we chose an almost isotropic film, (a) in Fig. 2, and an anisotropic one, (b) in Fig. 2. Table I shows fabricated MIG heads specifications, measurement conditions, and results. As predicted above, the output of the head using an anisotropic film is larger than the head using an isotropic film by 1.8 dB.

Contact magnetoresistive head for perpendicular magnetic recording

Ken-ichi Takano, Hiroaki Muraoka, and Yoshihisa Nakamura

Research Institute of Electrical Communication, Tohoku University, 2-1-1 Katahira, Aoba-ku, Sendai 980-77, Japan

Contact-type magnetoresistive (MR) inductive head designs and recording characteristics have been discussed in perpendicular magnetic recording. The shielded-type MR head offered a high D_{50} of 100–135 kFRPI, and the unshielded MR head had the largest output in a low density region. However when the recorded bit length became shorter than the shield-to-shield spacing, the shield had little effect and the output of the shielded head was no longer almost equal to that of the unshielded MR head. In result, the shielded-type and even unshielded-type MR heads have good high density recording characteristics in the head-to-medium contact state. © 1996 American Institute of Physics. [S0021-8979(96)08608-7]

I. INTRODUCTION

Magnetoresistive (MR) head technology makes it possible to perform high areal density magnetic recording over 1 Gbit/in.² (Refs. 1 and 2). The MR head is expected to offer a high density response as well as the large output for the sensor in future high linear and track density recording system. In a high linear density recording design, the low head-to-medium clearance and a high resolution medium have to be developed. On the other hand, extremely high resolution recording over 600 kFRPI has been characterized by using a perpendicular medium and a single-pole head in the head-to-medium contact state.³ Consequently the introduction of the contact perpendicular recording is expected to be an important technology in the high density design. A MR head for perpendicular recording is also a key element to a sensitive read head. However a few reports^{4,5} have been presented on readback performance of a MR head combined with a perpendicular medium. In this work the characteristics of perpendicular magnetic recording are described, obtained by the combination of contact MR heads and a perpendicular double-layered disk.

II. HEAD DESIGN

Generally a conventional MR head is optimized for longitudinal recording, which is combined with an inductive ring head and has a shielded MR element for the improvement of high density response.⁶ When a MR head is adopted for the read element in perpendicular magnetic recording, the single-pole head is preferable to the ring head from the view point of the write performance. Moreover the shield effect in the MR head is not sufficiently investigated for the perpendicularly recorded mode. Consequently the MR head for perpendicular recording has to be newly designed. Here we designed and fabricated three kinds of contact MR heads for perpendicular recording.

The schematic cross sections of the MR heads and the illustrations for the read/write elements used in the following experiments, are shown in Fig. 1. These heads have a writing single pole, an auxiliary core, and a read MR element. The auxiliary core is wound with a 26 turn coil, and the read/write elements are connected with the core.

Each MR element has a 25-nm-thick $\text{Ni}_{80}\text{-Fe}_{20}$ film biased by a soft adjacent layer (SAL). The sensor height of a

conventional flying MR head is typically 1–2 μm for high read sensitivity. However a sliding contact hard disk system⁷ gives rise to the wear of the air bearing surface (ABS) due to the head-to-disk contact, and here every MR sensor height is adjusted to approximately 10 μm . The sense current was set at 20 mA (current density: $0.3 \times 10^7 \text{ A/cm}^2$) in accordance with the output wave form asymmetry.

A. Unshielded-type MR head

The unshielded-type MR head Fig. 1(a) is composed of a MR read element and an inductive write element. These elements are arranged at intervals of 50 μm and magnetically separated from each other. The write pole is made of 0.4- μm -thick Co–Zr–Nb amorphous film. This pole, the MR element, and the lead line are exposed on the ABS. The track width of the MR read sensor is 3 μm , and the height is 10 μm .

B. Shielded-type MR head

The head shown in Fig. 1(b) has a MR element shielded on both sides. The shields made of Co–Zr–Nb film are 0.4

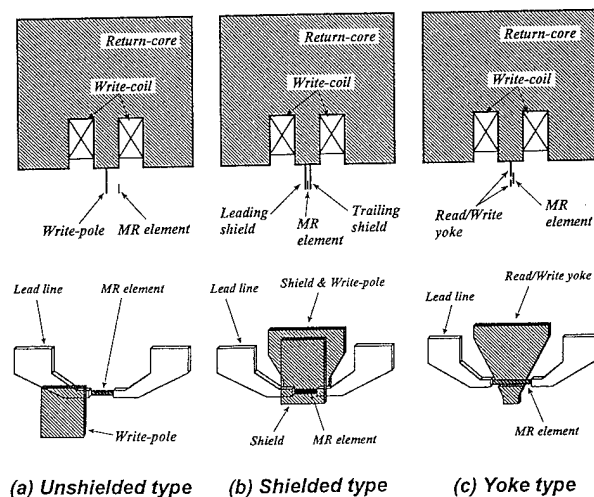

FIG. 1. The upper figures are the schematic cross sections of contact MR heads for perpendicular magnetic recording. The lower figures are schematic illustrations of the read/write elements of the MR heads.

TABLE I. Properties of the double-layered hard disk for the experiments.

Parameters	Values
Thickness of Co-Cr	50 nm
M_s of Co-Cr	496 emu/c
$H_{c(l)}$ of Co-Cr	1480 Oe
Thickness of Ni-Fe-Nb	0.5 μm
Thickness of SiO_2	4 nm
Substrate	Glass

μm thick, and are thinner than that of a conventional MR head. The trailing shield plays a part in the recording as an inductive write pole and defines the write track width. The shield-to-shield spacing, without the thickness of the MR and the SAL films, is 0.7 μm . The shields are also exposed on the ABS in addition to the MR element and lead line. The read width and height of the MR sensor are 3 and 10 μm , respectively.

C. Yoke-type MR head

A MR sensor is inserted into the yoke of the head shown in Fig. 1(c). The head construction is simple since the yoke performs the read and write operations as a flux guide, all in one. The yoke material is Fe-Si/SiO₂ multilayered film, and the yoke is only exposed on the ABS. The front yoke, whose thickness and width are 0.25 and 10 μm , respectively, guides the medium surface flux through the MR sensor. Both the front yoke width and height are 10 μm , and this track width is wider than those of the above-described MR heads.

III. MEASUREMENT CONDITIONS

The contact MR heads were evaluated on a Co-Cr/Ni-Fe-Nb double-layered hard disk. Table I shows properties of the medium for the following experiments. The disk was fabricated by sputtering a Cr underlayer, a Ni-Fe-Nb backlayer, a Co-Cr recording layer, and a SiO₂ protective layer on a flat glass substrate. The surface was given a coat of liquid lubricant (PFPE), which kept the electric insulation between the exposed MR element, the lead lines, and the disk surface. The measurements were performed at a relative velocity of 2 m/s, then the head-to-disk clearance was 30 nm.

Every head had adequate write performance, and especially in the shielded type, good overwrite characteristics were obtained since the leading shield operates as a shield from the stray field of the prewritten region.⁸ The readback performance of the MR heads was tested after the saturation recording. The mechanical rubbing noise and the thermal asperity were not detected in the contact state combined with the medium.

IV. READBACK PERFORMANCE

Figure 2 shows readback wave forms of the three types of heads at 10 kFRPI density. These wave forms were different from the one produced by longitudinal recording. Even in the unshielded MR head Fig. 2(a), the output had a very sharp slope at the rear side of a magnetic transition, and was

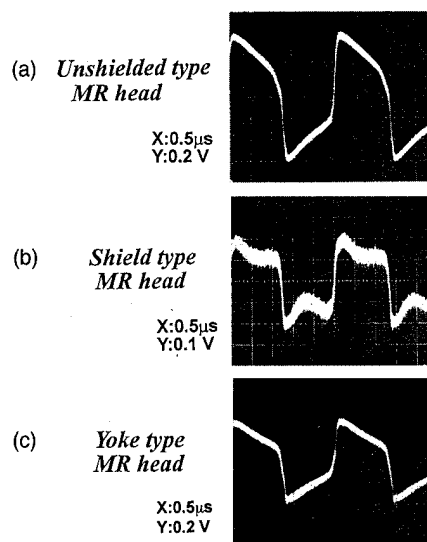

FIG. 2. Readback wave forms of MR heads at a linear density of 10 kFRPI. (a) Unshielded-type, (b) shielded-type, and (c) yoke-type.

gradually attenuated after the peak due to the medium demagnetization state and the high passage filter of 20 kHz cutoff frequency in the read amplifier.

On the other hand, the shielded MR head Fig. 2(b) had the wave form emphasized not only at the rear but also at the front of a transition. Since the surface demagnetization field is relieved in the vicinity of the transition, the peak appears at the front of the transition, too.

The yoke-type MR head Fig. 2(c) had almost the same wave form as the unshielded type, since the head did not have a shield. The wave form did not have the peak at the front side of the transition like the unshielded type head because of the stray field from the neighboring recorded region. These wave forms are related to the medium demagnetization state and the surface field gathering range by each contact MR head. However every wave form approached sine waves with increasing recording density.

We also measured the recording density characteristics. The rolloff curves differed according to the type of MR head, as shown in Fig. 3. In the unshielded-type head, the largest output of low density was obtained. This is because the MR sensor is situated on the medium surface and gathers the

FIG. 3. Density rolloff curves of MR heads with a sense current of 0.3×10^7 A/cm².

medium field widely. This stray field decreased and the output gradually decreased with increasing recording density. However this output decrease was smaller than the theoretical MR height loss,⁹ considered just nonmagnetic space. The actual MR height loss must be quite tiny.

On the other hand, the shielded-type MR head gathered only the medium surface field of the shield-to-shield region and the output was lower than that of the two heads in low density. However the head showed the highest D_{50} of 100 kFRPI, and it was increased to 135 kFRPI by adopting a 0.5 μm shield-to-shield spacing. However the experimental result was not in agreement with the theory characterized by spacing loss and gap loss, and the output of the shielded head was almost equal to that of the unshielded MR head in high density region. This is because the shielded MR head cannot be always regarded as two back-to-back ring heads,⁶ and the MR element must operate independently, particularly in high density region.

The yoke-type MR head also gathered the surface stray field far from the recorded region and showed large output in low density, though its MR element was remote from the medium surface. However the output decreased gradually in low density and rapidly in the range over 50 kFRPI with increasing recording density, because of the yoke thickness loss and the decrease of the stray field. The thinner front yoke must be adopted for high density response.

Both the shielded- and unshielded-type MR heads have high read sensitivity in a high density recording region. In fact, the 500 kFRPI signal was confirmed in these MR heads.

V. SUMMARY

We designed and fabricated the newly developed contact MR heads for perpendicular magnetic recording. They were evaluated with a double-layered hard disk in order to exam-

ine the operation of the MR element and the shield in the contact state. The shielded-type, unshielded-type, and yoke-type heads offered square waves with the sharp slope at the transition. Though the construction of the yoke-type MR head was simple, the head showed poor high density resolution because of the yoke thickness loss. In contrast, each read element of the unshielded and shielded MR heads is so thin that the thickness loss can be practically negligible. The shielded-type and even unshielded-type MR head had good high density characteristics. The shield, which was considered necessary for a high density response, had little effect when the recorded bit length became shorter than the shield-to-shield spacing. The output of the shielded-type head was almost as large as that of the unshielded type in the high density region in the case of the head contact, because of the independent operation of the MR element in both heads. We conclude that the combination of a contact MR head and a perpendicular medium offers the possibility of a future high density storage system.

Magnetostriction and thin-film stress in high magnetization magnetically soft FeTaN thin films

M. K. Minor, B. Viala, and J. A. Barnard

Department of Metallurgical and Materials Engineering and The Center for Materials for Information Technology, The University of Alabama, Tuscaloosa, Alabama 35487-0202

Domain structures in thin-film heads can be significantly influenced by magnetoelastic anisotropy. In this study we have undertaken systematic measurements of magnetostriction and stress in as-deposited and annealed states in FeN and FeTaN single-layer thin films with varying nitrogen contents. Magnetostriction was positive for FeN films, increased with increasing nitrogen content, and shifted toward negative values after annealing. Stress in as-deposited FeN films was tensile and decreased (became more compressive) with increasing nitrogen content. Annealing the FeN films resulted in significant stress relief. By contrast, magnetostriction was found to be negative for simple FeTa (zero nitrogen) and increased linearly with increasing nitrogen content to positive values. The magnetostriction in FeTaN did not change significantly after annealing at 200 and 250 °C. FeTaN film stresses were compressive in the as-deposited state and increased in magnitude (became more compressive) with increasing nitrogen content. After annealing these stresses were relieved slightly. Ta has been found to be very effective in enhancing the thermal stability of the FeN films. © 1996 American Institute of Physics. [S0021-8979(96)08708-3]

I. INTRODUCTION AND EXPERIMENTAL METHODS

An extremely important factor in optimizing the performance of thin-film recording heads is the control of domain structures. Domain structures in thin films are controlled by the magnetoelastic anisotropy which is proportional to the product of the film stress (σ_f) and saturation magnetostriction. The relationship between domain structures and magnetoelastic anisotropy in FeTaN thin films has recently been studied.¹⁻³ In this article, film stress and magnetostriction in both FeN and FeTaN films have been studied as a function of nitrogen content for as-deposited and annealed states.

Nanocrystalline, single-layer FeN and FeTaN films were deposited at ambient temperature by dc magnetron reactive sputtering in a Vac-Tec Model 250 Sputtering System. The films were grown on oxidized silicon wafers with a (100) orientation in an aligning field of ~70 Oe to induce uniaxial anisotropy. 4" diameter Fe and Fe-10 w/o Ta targets were used. The 10 w/o target produced films with ~3.2 a/o Ta. All films were grown at a fixed power of 220 W and a fixed Ar pressure of 3 mTorr. Nitrogen content was controlled by varying the flow rate (sccm) of a 90 Ar-10 N₂ gas mixture. These conditions produced growth rates of ~640 Å/min with the pure Fe target and ~730 Å/min with the Fe-10 Ta target. Films ranged from 4600 to 6000 Å thick. Films were vacuum annealed for 30 min at 200 and 250 °C in a 200 Oe aligning field in a vacuum ($<5 \times 10^{-6}$ Torr). Film stress was measured on a Flexus 2320 thin-film stress measurement system. Film structure was studied using x-ray diffraction (XRD) performed on a Rigaku D/Max-2BX XRD system. Coercivities were measured on a SHB Instruments Model 106 loop tracer. Saturation magnetostriction was measured in an ac magnetostriction tester.⁴

II. EXPERIMENTAL RESULTS AND DISCUSSION

X-ray diffraction revealed that the as-deposited and annealed FeN and FeTaN films have the α -Fe structure with a

(110) growth texture. This corresponds to a single-phase bcc film structure with N dissolved interstitially and Ta dissolved substitutionally.^{5,6} No evidence was found by XRD for the existence of iron nitride or tantalum nitride phases but small volume fractions would be difficult to detect using XRD. TaN phases were identified by means of transmission electron microscopy (TEM) cross-sectional examinations in both as-deposited and annealed FeTaN films. The early stage of the homogenous nucleation of fcc TaN coherent particles (10 Å) has been observed around 2.5 sccm N₂ flow rate in as-deposited FeTaN films. Annealing temperatures higher than 300 °C have been found to promote the nucleation and growth of this phase. TaN phases also have been observed in similar materials by others.¹

Figure 1 shows the d spacing of (110) planes, d_{110} , versus nitrogen flow rate for the FeN and FeTaN films in the as-deposited and annealed states. Several features stand out in Fig. 1. At zero nitrogen, d_{110} is larger in magnitude for FeTa than for Fe. This lattice expansion can be explained by the presence of substitutional Ta atoms, according to Vegard's law. In liquid FeTa alloys, the measured lattice dilation (56.28×10^{-4} /at. % Ta) is within 10% of Vegard's Law prediction.⁷ Our measurement is in good agreement with this result. Figure 1 also indicates that d_{110} increases as nitrogen flow rate increases. This result is expected because when more nitrogen is available in the sputtering plasma, more nitrogen is incorporated into the interstitial lattice sites during growth. Increased interstitial nitrogen results in the lattice expansion. Figure 1 also indicates that d_{110} decreases upon annealing. This is due to stress relief and/or defect annihilation in the films. The FeN films undergo significantly greater lattice contraction than their FeTaN counterparts. This indicates that Ta stabilizes the lattice structure.

Another clear feature is that the FeTaN films incorporate more nitrogen than the FeN films for the same sputtering conditions, i.e., the rate of increase of d spacing with N₂ flow is higher for FeTaN than FeN films. The FeTa lattice has a

FIG. 1. Dependence of lattice spacing d_{110} on nitrogen flow rate for FeN and FeTaN films in the as-deposited and annealed (200 and 250 °C) states.

higher affinity for nitrogen than the pure Fe lattice. The solubility of nitrogen in a number of binary liquid alloys has been extensively studied.⁸ Refractory metals such as Ti, Zr, Va, and Ta markedly increase the solubility of nitrogen in liquid iron. Nitrogen "roughly" obeys Sievert's law in Fe sputtered in nitrogen-rich plasma, $a/o \ N \propto P(N_2)^{0.5}$, where $P(N_2)$ represents the nitrogen partial pressure in the sputtering gas environment. An estimate of the nitrogen concentration in the films was made on the basis of the measured lattice expansion using published data.⁹ Extending this line of reasoning, the nitrogen incorporation in the presence of 10 w/o Ta has been evaluated using the interaction coefficient for Ta, $e^{Ta}(N) = -0.034$, measured in the liquid alloy.⁸ Experimental results shown in Fig. 2 reveal a good agreement

FIG. 2. Theoretical and experimental dependence of lattice spacing d_{110} on nitrogen flow rate in Fe-10 w/o TaN.

FIG. 3. Film stress vs at. % N for FeN and FeTaN films in the as-deposited and annealed (200 and 250 °C) states.

with the predicted nitrogen content up to 1 sccm N_2 flow rate for FeTaN. Higher nitrogen flows leads to a discrepancy which is consistent with the observed onset of nucleation of TaN phases.

Average grain sizes were estimated from the FWHM of the (110) peak (not shown). The grain size was found to decrease with increasing nitrogen content. The average grain sizes ranged from 110 to 83 Å for the FeN films and from 160 to 100 Å for the FeTaN films. Average grain size in the FeN films increased 25%–45% after annealing at 200 °C and 30%–55% after annealing at 250 °C. On the other hand, the FeTaN films showed less than 10% average grain size increase after annealing at 200 °C and no appreciable growth

FIG. 4. Magnetostriction vs at. % N for FeN and FeTaN films in the as-deposited and annealed (200 and 250 °C) states.

FIG. 5. Magnetoelastic anisotropy vs at. % N for FeN and FeTaN films in the as-deposited and annealed (200 and 250 °C) states.

after the second anneal at 250 °C. This is another indication of the stabilizing effect of Ta.

Figure 3 shows film stress versus N content for FeN and FeTaN films. FeTaN films contain about three times as much interstitial nitrogen as FeN films grown under the same conditions. All as-deposited FeN films were in a state of tension and the magnitude of the tensile stress increased substantially with annealing. By contrast, as deposited FeTaN films were in a state of compression and while annealing resulted in stress relaxation, the sign of the stress remained compressive. Ta is a larger atom than Fe (~16% larger) and its substitution into the Fe lattice causes lattice strains which result in a more compressive stress state compared to FeN. Although N is incorporated interstitially in both the FeN and FeTaN, both the interstitial N and substitutional Ta act to expand the lattice in the FeTaN and this generally makes the FeTaN more compressive than the FeN. FeN films undergo much more stress relaxation after annealing than the FeTaN films, as another indication of the stabilizing effect of Ta.

Figure 4 shows saturation magnetostriction λ_s versus at. % N for as-deposited FeN and FeTaN films in both as deposited and annealed states. (After annealing the FeN films at 200 and 250 °C, λ_s could not be achieved because the films could not be saturated. λ_s values reported for FeN films after annealing are taken at 60 Oe.) The FeN films have a more positive λ_s than the FeTaN films in the as-deposited state. Upon annealing, the values of λ_s for the FeN films become more negative. This change is consistent with the growth of the (110)-oriented grains which have an average negative λ_s . The values of λ_s for the FeTaN films increase

from negative to positive with increasing nitrogen content as reported previously.¹⁰ These values do not change appreciably after annealing at 200 and 250 °C. The general increase in λ_s with N content is consistent with our previous work.^{2,10} Here again, Ta clearly stabilizes the lattice structure and increases the thermal stability.

Figure 5 shows magnetoelastic anisotropy, $(3/2) \lambda_s \sigma_f$, versus at. % N for the FeN and FeTaN films in both the as-deposited and annealed states. The as deposited FeN films have a positive magnetoelastic anisotropy due to both positive stress and magnetostriction. The magnetoelastic anisotropy for the FeN films changes dramatically after annealing. The values become negative and all annealed FeN films exhibit *M-H* loops characteristic of stripe domains. This is due to a favored perpendicular anisotropy component resulting from the increasing tensile stress and decreasing magnetostriction. The FeTaN films exhibit a curve which is negative for the as-deposited state and does not change significantly with annealing. The high nitrogen, ~5 a/o, FeTaN films exhibited *M-H* loops characteristic of stripe domains, however, no stripe domains were evident after annealing at 250 °C. The combination of the linear increase of the positive magnetostriction with the increase of the compressive stress leads to an increasingly negative magnetoelastic anisotropy with nitrogen incorporation for FeTaN. It has been observed that the FeTaN films exhibit a well defined columnar structure which becomes finer as nitrogen is added, leading to a decrease of the shape anisotropy. In these conditions, a perpendicular anisotropy component appears promoting the formation of stripe domains, experimentally observed in the range of 5 a/o N in as-deposited and 200 °C annealed FeTaN films. After annealing at 250 °C, the stripe domains disappear mainly because of the reduction of the magnetoelastic anisotropy due to the decrease of the compressive stress.

Exchange coupling between NiO and NiFe thin films

J. X. Shen and M. T. Kief^{a)}

Department of Physics and Astronomy, P.O. Box 870324, University of Alabama, Tuscaloosa, Alabama 35487-0324

NiO/NiFe bilayer thin films were prepared by rf reactive and dc magnetron sputtering, respectively. The exchange coupling strength between NiO and NiFe as a function of NiO texture and interface roughness was investigated by using different sputtering pressures, Au, and Cu buffer layers. The experimental results show that the exchange coupling field strongly depends on the NiO/NiFe interface roughness. In addition, we found the exchange coupling is largest for the (200) texture compared to the (111)-texture films. This is surprising since the bulk spin structure of NiO predicts the (200) plane to be compensated while the (111) plane is to be uncompensated. © 1996 American Institute of Physics. [S0021-8979(96)14408-0]

I. INTRODUCTION

Investigations of exchange coupling between antiferromagnetic and ferromagnetic thin films have been carried out for several decades because of the interest both in physics and technology (for example, the magnetoresistive recording head).¹⁻⁵ However, many questions concerning this exchange coupling remain unanswered. In particular, the simplest models predict an exchange coupling strength typically 100 times greater than that observed in experiments. Recently, two models have been proposed by Mauri⁶ and Malozemoff⁷ to quantitatively explain this phenomenon. In Mauri's model, the antiferromagnetic film forms a domain wall along the interface to minimize the free energy of the system during the reversal of the ferromagnetic film under an applied magnetic field. In order to have exchange coupling, parallel spin configuration in the antiferromagnetic film at the interface is assumed. In Malozemoff's model, the antiferromagnetic film breaks up into domains due to the roughness at the interface and the domain walls are perpendicular to the interface. In this case, a completely parallel (uncompensated) spin configuration at the interface is not necessary and the roughness in the interface is very important. In this paper, we report how the texture and interface roughness of the antiferromagnet (NiO) affects the exchange coupling in the NiO/NiFe system.

II. EXPERIMENT

All films in this study were prepared in our Vac-Tec four-cathode sputter system with a base pressure of 5×10^{-7} Torr. All samples were prepared as follows: Substrate [Corning Glass 7059, Si(111) wafer]/buffer layer (if used)/NiO/NiFe. NiO was deposited by rf reactive ion sputtering from a Ni target in the mixture of O₂ and Ar gases. The ratio of the O₂ to Ar was regulated by two mass flow controllers and confirmed by residual gas analyzer. Single-phase NiO thin films, as evidenced by x-ray diffraction measurements, could be obtained with the O₂ to Ar ratio of 6%–20%. However, maximum exchange coupling between NiO and NiFe occurred for the films sputtered at an 8% O₂-Ar ratio.

Ni₈₀Fe₂₀, Au, and Cu thin films were prepared by dc sputtering with 99.99% pure Ar at a pressure of 2.5 mTorr. A permanent magnet which produced a magnetic field of ~ 80 Oe along the substrate surface was present during the deposition process. This field produced an easy axis in the NiFe film and defined the exchange coupling axis. X-ray diffraction was used to characterize the crystalline properties of the films and the roughness was determined by atomic force microscopy (AFM). The magnetic properties were measured using both a vibrating sample magnetometer (VSM) and a B-H loop tracer. All the measurements were conducted on the as-deposited samples. The exchange coupling field defined by the asymmetric shift of the ferromagnet hysteresis loop from zero applied field was determined after many cycling of measurements to ensure that no noticeable aftereffect was present.

III. RESULTS AND DISCUSSION

Figure 1 shows the exchange coupling field (H_E) of 200 Å NiFe films deposited on 300 Å NiO thin films with glass substrate as a function of NiO sputtering pressure. The H_E increases rapidly with decreasing sputtering pressure of O₂

FIG. 1. Exchange coupling field of glass/NiO 300 Å/NiFe 200 Å as a function of NiO sputtering pressure.

^{a)} Author to whom correspondence should be addressed.

FIG. 2. X-ray diffraction patterns for glass/NiO 300 Å films prepared at different sputtering pressures.

and Ar. The AFM measurements of NiO films prepared at the same time as the above films show that the roughness of the NiO surface increases with increasing sputtering pressure. The rms roughness determined by AFM over an area of 500 nm² varied from 7 to about 14 Å when the sputtering pressure increased from 1.5 to 10 mTorr, respectively. Therefore, the exchange coupling was found to increase with decreasing rms roughness of NiO interface. Unfortunately, the texture of the NiO thin films also changes with the sputtering pressure. Figure 2 shows the high angle x-ray diffraction patterns of NiO films sputtered at different pressures. At 10 mTorr, there is a strong (111) diffraction peak and no (200) peak is detectable. With decreasing Ar/O sputtering pressure, the NiO (111) peak gradually decreases and by 1.5 mTorr, the (111) diffraction peak has almost totally disappeared. The NiO (200) diffraction peak gradually increases with decreasing sputtering pressure. For NiO sputtered at 1.5 mTorr, the texture of the NiO is almost totally (200). These data show that the increase of H_E with decreasing sputtering pressure could be due to the decreasing roughness of the NiO interface (Fig. 1) or due to the increase of the NiO (200) texture (Fig. 2) or both. This result is somewhat surprising, when we consider that the spin structure of bulk NiO (Ref. 8) predicts the NiO (100) plane is the spin compensated plane (i.e., no net in-plane moment), while the NiO (111) is the spin uncompensated plane (i.e., maximum in-plane moment). Neglecting roughness, Mauri's model would predict that the exchange coupling would be zero for the NiO (200) orientation. Of course, this prediction assumes perfectly flat and abrupt interfaces which the AFM shows to be a poor description of the real films. In order to investigate the independent effects of texture and roughness on the exchange coupling further one must separate these two factors. In order to vary the roughness and texture independently, we used Au buffer layers to promote the (111) texture of NiO and Cu buffer layers to alter the roughness of the NiO while maintaining the (200) texture.

FIG. 3. X-ray diffraction patterns for glass/Aux Å/NiO 300 Å/NiFe 200 Å thin films.

Sputtered Au generally has a strong (111) texture and the lattice mismatch of Au(111) and NiO(111) is modest (2.2%). Therefore, it can be expected that the texture of the NiO may copy the texture of the Au buffer layer. Figure 3 shows the x-ray diffraction pattern of glass/Aux Å/NiO 300 Å/NiFe 200 Å thin films with the Au buffer layer thickness x varying from 20 to 1000 Å. The sputtering pressure of NiO is 2 mTorr. Two features are worth noting: (i) the NiFe and Au(111) diffraction peaks increase with increasing Au buffer layer thickness. (ii) The NiO(111) diffraction peak of NiO increases relative to the (200) diffraction peak with increasing Au buffer layer thickness. The NiO films change from weak texture for a very thin Au buffer layer to almost complete (111)-texture for a very thick Au buffer layer, possibly due to the epitaxy of the NiO on the Au. Figure 4 plots the exchange coupling field as a function of the ratio of (111) diffraction intensity to (200) diffraction intensity. Surpris-

FIG. 4. Exchange coupling field as a function of NiO (111) and (200) diffraction peak intensity ratio, for the samples of Fig. 3.

FIG. 5. Exchange coupling field of NiO 300 Å/NiFe 200 Å as a function of rms roughness of NiO thin film. (●) Si/Cu 500 Å/NiO 300 Å/NiFe 200 Å, in which NiO prepared under 1.5 mTorr and 150 W. (×) Glass/NiO 300 Å/NiFe 200 Å, in which NiO prepared at different sputter pressure.

ingly, H_E barely changes with the change of the texture of NiO. Similar results were found in the FeF_2 -Fe exchange coupling system.⁹

Next we investigated the role of the interface roughness for nearly constant texture. A 500 Å Cu buffer layer was sputtered on Si(111) with varying sputtering pressure. The surface of the Cu buffer layer is expected to change from very smooth at lower sputtering pressure to very rough at high sputtering pressure. A 300 Å NiO film was deposited onto the Cu buffer layer at a pressure of 1.5 mTorr and power of 150 W to produce a NiO (200) texture. Since the lattice mismatch between Cu and NiO is quite large, the change of texture in the Cu buffer layer should not strongly affect the texture of the NiO films. Finally, 200 Å NiFe film is deposited onto the NiO/Cu/Si samples. The x-ray diffraction pattern confirms that NiO has the desired (200) texture and this texture appears nearly independent of the Cu buffer layer. The roughness of the NiO increases with Cu sputter pressure from 1.5 to 15 mTorr, as measured by AFM. Without the Cu buffer, very smooth and almost featureless NiO surfaces can be realized, with rms roughness of ~ 1 Å over a $1 \mu\text{m}^2$. With the Cu buffer layer, the NiO is much rougher, reaching a

maximum rms roughness of 8.4 Å for the Cu sputtered at 15 mTorr. Figure 5 plots the exchange coupling H_E , as a function of the rms roughness for these NiFe/NiO/Cu/Si samples (circles) and the NiFe/NiO/glass for varying sputter pressures (crosses). The NiO texture varies from entirely (200) for the smoothest films to entirely (111) for the roughest films. Figure 5 indicates that the highest H_E are obtained for the smoothest NiO. Recalling Fig. 4 which showed the very weak or no dependence of H_E on NiO texture, we are led to conclude that H_E is dominated by the interface roughness for the NiO/NiFe system. Presently, we cannot say if this conclusion is fundamental or practical in origin. In other words, roughness may always be the controlling factor in determining H_E or it may be experimentally difficult to produce flat NiO films with (111) texture. Further experiments to answer this question are underway.

IV. CONCLUSIONS

We have shown that the exchange coupling between NiO and NiFe is strongly dependent on the interface roughness. Although this result is not unexpected, it is surprising that H_E is found to be much larger for the compensated (200)-textured NiO film than the uncompensated (111)-textured NiO film. Finally, it should be emphasized that future models of antiferromagnet/ferromagnet exchange coupling must include more realistic representations of the interface topology, most interfaces have large features comparable to the AFM domain wall width (~ 100 nm), not simply atomic vacancies or defects.

Search for high moment soft magnetic materials: FeZrN (abstract)

A. Chakraborty, G. H. Bellesis, K. R. Mountfield, D. N. Lambeth, and M. H. Kryder
Data Storage Systems Center, Carnegie Mellon University, Pittsburgh, Pennsylvania 15213-3890

FeN materials exhibiting high moment, low coercivity and small magnetostriction have previously been reported. Zr has been known to reduce the magnetostriction in other Fe alloys. The criteria for an ideal recording head pole material as well as shields for magnetoresistive sensors include high moment, low coercivity, high permeability, and zero magnetostriction. We present here the properties of half micrometer thick rf sputtered FeZrN films on glass coupons. The films were deposited at a pressure of 3 mTorr using a Perkin-Elmer sputtering system. The target was composed of Fe with Zr chips covering approximately 2% of the surface area. The properties were measured as a function of the N₂ partial pressure. The saturation magnetization of the as-sputtered films was approximately 20 kG. The easy axis and the hard axis coercivities show minima at approximately 7%–10% N₂ partial pressure of approximately 1.8 and 0.6 G, respectively. The magnetic anisotropy is approximately 5 G yielding a dc permeability of approximately 4000 along the hard axis. X-ray data reveal a systematic change in the ratio of α -Fe and γ -Fe₄N; the amount of the γ -Fe₄N phase increases with increasing N₂ flow rate. The magnetostriction increases with increasing N₂ content crossing zero at approximately 6%. The grain size as probed by atomic force microscopy is an increasing function of the N₂ partial pressure, from a few nm for a N₂ partial pressure of 5% to as large as 50 nm for a N₂ partial pressure of 15%. © 1996 American Institute of Physics. Magnetic properties of CoFeB sputtered films for high Bsat applications (abstract)

Durga Ravipati, Hua-Ching Tong, and Lena Miloslavsky
Read Rite Corporation, Fremont, California

High density recording requires pole material with a large saturation magnetization and high permeability. To realize the high data rate and high frequency (in the range of 40–100 mHz) applications in thin film heads, high resistivity materials are desired.¹ Amorphous materials such as CoZrNb, CoHfNb, etc., and crystalline materials such as FeAlN, FeN, etc., were studied for high Bsat applications.^{2–4} CoFeB films were rf sputter deposited on Al₂O₃–TiC substrates. The as-deposited Hce (easy axis coercivity), Hch (hard axis coercivity) anisotropy field Hk and magnetostriction λ_s were measured to be 0.05–0.10, 0.19–0.31, 16–21 and -6.5×10^{-7} , respectively, with a saturation magnetization of 15.4 kG. The as-deposited magnetic anisotropy Hk was reduced to 2.5 Oe by vacuum annealing the wafers in a rotating external magnetic field of ~ 6000 Oe at 200 °C. Reduction of Hk by RFA can be attributed to magnetic field thermally induced pair ordering. A 1 μ m thick CoFeB film exhibited resistivity of 66 $\mu\Omega$ cm compared to 22 $\mu\Omega$ cm for NiFe plated films. The high resistivity helps in reducing eddy current losses which do impede the uniform reversal of magnetization in the films. The amorphous structure was observed to be stable to 250–275 °C and changes to crystalline structure above 300 °C. Details on corrosion properties and x-ray diffraction data will be presented. © 1996 American Institute of Physics. [S0021-8979(96)45508-X]

Exchange coupling of sputter deposited NiCo–O/NiFe thin films

Minshen Tan, Hua-Ching Tong, Swie-In Tan, and Robert Rottmayer
Read-Rite Corporation, 44100 Osgood Road, Fremont, California 94539

NiCo–O serving as the exchange layer in a spin valve structure has the advantage of being corrosion resistant and unable to shunt sensing current in the read element. In this work, NiCo–O/NiFe thin films are studied. The films are deposited on Si wafers using rf sputtering. The antiferromagnetic NiCo–O films were reactively sputtered from alloy targets; one has a 55 at. % of Co and the other 60 at. % of Co. The chamber atmosphere is an Ar/O₂ mixture containing ~10% O₂. For films with optimal structures, the exchange strength is around 40–45 Oe. The coercivity of the pinned layer is between 18–26 Oe. The exchange strength and coercivity as a function of NiCo–O thickness (with NiFe thickness fixed at 200 Å) and NiFe thickness (with NiCo–O fixed at 250 Å) are examined. The exchange field is found to increase with the antiferromagnet thickness initially and then flatten out or drop slightly when the antiferromagnet thickness is beyond 200–250 Å. Blocking temperature of the bilayer films is also measured, and is found to increase with NiCo–O thickness. NiCo–O with lower Co content shows slightly higher blocking temperature. © 1996 American Institute of Physics. [S0021-8979(96)08808-X]

I. INTRODUCTION

The demand for ever-increasing storage density in the data storage industry calls for new recording technology. Spin valve/giant magnetoresistive (GMR) read head is the next generation beyond magnetoresistive (MR) heads, which operates on a magnetic anisotropy mechanism. The spin valve/GMR effect occurs mostly in a layered structure consisting of at least a sandwich with one conducting spacer (S) separating two ferromagnetic (FM) layers. The conduction electrons preserve their spin orientation of the magnetization in the original magnetic layer where they are from when they move across the spacer and enter into the neighboring magnetic layer. Depending on the magnetization orientation in the new layer, the electrons can be either highly scattered if the spin orientation has a large angle with respect to the local magnetization, or lightly scattered if the aforementioned angle is small. The film structure's electrical resistance will then be different. In a spin valve head with a structure of AFM/FM1/S/FM2 the magnetization of FM1 is fixed at one direction by the exchange coupling with an antiferromagnetic layer attached to it. The other magnetic layer (FM2) will have a uniaxial anisotropy perpendicular to FM1. The electrical resistance, and ultimately the signal output, of the sensor is then a function of the cosine of the relative angle between the two magnetization vectors as it dictates the spin dependent scattering of the conduction electrons. Large exchange coupling strength between the so-called "pinned" ferromagnet FM1 and the "pinning" antiferromagnet (AFM) has then become one of the core technologies in the spin valve heads. The exchange pinning layer has received extensive study.^{1–5} In the early stage of spin valve head development, antiferromagnetic alloy materials such as FeMn, NiMn, and TbCo were used as the exchange pinning layer, partially inherited from the exchange biasing scheme in MR technologies. However, the poor corrosion properties of these alloys posed serious problems for head manufacturing. To address the corrosion resistance, nonconducting oxide materials emerge as the choice for pinning materials.^{1,3,4} Most studied are oxides of ferromagnetic metals and alloys,

such as NiCo–O, Ni–O, or Co–O. These oxide materials possess excellent corrosion resistance and, because they are nonconducting, the current shunting effect during read process is also minimized and the signal output is enhanced. In this article, the sputter deposition of NiCo–O of different NiCo compositions will be discussed. Magnetic properties of NiCo–O/NiFe exchange coupled films will be investigated, together with the microstructural and crystal structure of the films.

II. EXPERIMENT

NiCo–O/NiFe thin films were deposited by sputtering in a rf diode system. The bilayer films were deposited on 3 in. Si wafers. NiCo–O was reactively sputtered from NiCo alloy targets, one with 55 at. % Co, and the other with 60 at. % Co. The Ar/O₂ mixture contained roughly 10% vol. O₂, maintained by mass flow controllers. A downstream pressure control system was used to maintain the set chamber pressure. The pressure for NiCo–O deposition was kept at 2 mTorr. The base pressure of the system was $(2–3) \times 10^{-7}$ Torr.

The exchange field, H_{ex} , and coercivity, H_c , were measured by an SHB 108 loop tracer. A Lakeshore 7300 vibrating-sample magnetometer (VSM) equipped with a low vacuum heating furnace was used to measure the blocking temperature of the NiCo–O/NiFe bilayer exchange couples. Hysteresis loops could also be obtained while the sample was heated. An x-ray diffractometer (XRD) was used to obtain microstructure and crystal structure information.

III. RESULTS AND DISCUSSIONS

A. NiCo–O t Å/NiFe 200 Å films

In this series of samples, NiCo–O (Co 55 at. % and 60 at. %) was reactively sputtered, and the thickness varied from 100 to 400 Å with 50 Å increment. NiFe films were fixed at 200 Å thick. The exchange field and coercivity of the samples were listed in Table I, and the exchange field versus NiCo–O thickness data were plotted in Fig. 1. It agreed with previous work that exchange field initially increased with

TABLE I. Magnetic properties of NiCo-O t Å/NiFe 200 Å.

$t_{\text{NiCo-O}}$ (Å)	Co 55 at. %		Co 60 at. %	
	Hex (Oe)	Hc (Oe)	Hex (Oe)	Hc (Oe)
100	34.2	29.3	15.3	47.1
150	44.4	26.6	27.4	44.6
200	41.5	24.9	37.6	39.2
250	42.5	20.5	36.4	33.0
300	41.3	20.3	32.7	30.4
350	41.5	21.4	32.6	28.2
400	42.5	18.5	32.3	27.7

antiferromagnet thickness and this tendency flattened out when the AFM thickness reached around 200 Å and beyond. The slight fluctuation (within a few Oe) of the exchange field beyond that thickness is believed to be due to the sample fluctuations and measurement precisions. Extrapolating to the thin thickness side, the exchange strength quickly “dies out” when antiferromagnet thickness drops below 50 Å, as revealed by other researchers.^{2,3} However, although the exchange field was small at the thin NiCo-O end, the high coercivity indicated that the AFM/FM interaction still exists. While it is not very surprising to see that, in general, Co 60% films result in smaller H_{ex} and higher H_c throughout the spectrum of NiCo-O thickness compared with Co 55% samples, it is interesting to note that coercivity to exchange field ratio is much more undesirable for Co 60% films than those for Co 55%. For $t_{\text{NiCo-O}}$ up to 200 Å, Co 60% samples have coercivity larger than the exchange strength. Cobalt's high anisotropy constant is believed to be the cause for higher coercivity in the Co-rich samples. It is also interesting to note that in both series of the samples coercivity actually decreased while the exchange field became larger. This will be discussed further in Sec. III C.

B. NiCo-O 250 Å/NiFe t Å films

Another series of NiCo-O/NiFe samples were made by fixing the NiCo-O thickness at 250 Å. The NiFe layer thick-

FIG. 1. Exchange field vs NiCo-O thickness for NiCo-O 250 Å/NiFe 200 Å films.

FIG. 2. Exchange field vs NiFe thickness for NiCo-O 250 Å/NiFe t Å films.

ness was changing from 50 to 200 Å at an increment of 50 Å. The exchange field strength sharply increased as the NiFe thickness reduced, as predicted by Malozemoff⁶ in Eq. (1),

$$H_{\text{ex}} = \Delta\sigma / 2M_F t_F, \quad (1)$$

in which H_{ex} is the exchange field strength, $\Delta\sigma$ is the energy difference per unit area at the FM/AFM interface, and M_F and t_F are the magnetization and thickness of the ferromagnetic material. The coercivity of the films also increased drastically with thinner NiFe layers. It seemingly outpaced the increase of H_{ex} as the NiFe thickness was as thin as 50 Å. This rapid increase in coercivity is believed to be due to the films being less continuous, less crystalline, for thinner NiFe films. The data were shown in Fig. 2.

C. Blocking temperature of the NiCo-O/NiFe films

The Lakeshore 7300 VSM with a heating tube was used to measure the blocking temperature, T_b , of the exchange coupled films. Heating was conducted under vacuum to prevent oxidation of the films. Hysteresis loops were recorded at each temperature and exchange field and coercivity were measured from the loops. Blocking temperature is determined at the point when the coercivity of the film was close to what a typical NiFe film is supposed to be, ~ 1.5 –2 Oe, and the loop is symmetric. It was found for the NiCo55-O/NiFe 200 Å series that blocking temperature increases monotonically with the NiCo-O thickness. And the Co 55% sample has a higher blocking temperature than Co 60% sample. The results are shown in Fig. 3. Although exchange coupling is an interfacial phenomenon, it is obvious from what was described here in the blocking temperature versus NiCo-O thickness data, as well as what was previously shown in Table I and Fig. 1, that the whole antiferromagnet layer exerts its influence on the interfacial behaviors of NiCo-O/NiFe films. These behaviors are more complicated than H_{ex} vs NiFe thickness, which is relatively well understood by Eq. (1). While the Néel temperature is a characteristic of a particular material, the blocking temperature is associated with the Néel temperature ($T_b < T_N$) but may vary depending on different process and processing parameters. As the thickness of NiCo-O increases, the grains grow and, as a result, magnetic interactions become more coherent

FIG. 3. Blocking temperature vs NiCo-O thickness.

among the grains and domains. This is most likely the reason behind the $T_b - t_{\text{NiCo-O}}$ relationship demonstrated in Fig. 3.

D. Microstructural analysis by XRD

X-ray diffraction was performed on selected samples. Overall, the films showed a broad, weak NiFe(111) peak in the $\theta-2\theta$ scan, an indication of a weakly textured structure of the films. Weakly textured NiCo-O(111) was seen only in the sample with NiCo-O thickness of 400 Å. The NiFe texture was stronger in samples with thicker NiCo-O underneath than those with thinner NiCo-O films. Figure 4 shows both the 2θ (i.e., the grazing angle scanning mode for thin films) and $\theta-2\theta$ scans of the NiCo-O 400 Å/NiFe 200 Å sample and the 2θ scan of the NiCo-O 250 Å/NiFe 200 Å sample. The grain size is estimated by using Scherrer's formula⁷

$$t = 0.9\lambda_x / (\Delta 2\theta) \cos \theta_B, \quad (2)$$

where t is the grain size, λ_x is the wavelength of the incident x-ray beam, $\Delta 2\theta$ is the full width at half maximum (FWHM) of the diffraction peak, and θ_B is the Bragg's angle of the particular diffraction plane. For the sample with NiCo-O thickness of 250 Å, NiCo-O and NiFe grain sizes are estimated as 59 and 107 Å, respectively; and for the NiCo-O 400 Å sample, they are 92 and 143 Å, respectively.

FIG. 4. XRD scans for NiCo-O/NiFe films.

IV. CONCLUSIONS

NiCo-O/NiFe thin films were prepared by rf sputtering. NiCo-O was reactively sputtered. NiCo55-O outperforms NiCo60-O in terms of larger exchange strength, smaller coercivity, as well as thermal stability. Higher blocking temperature in samples with thicker NiCo-O films (NiFe thickness fixed) is probably due to the fact that the NiCo-O in these thicker films has larger grain size and a more coherent microstructure, as indicated by x-ray diffraction results. Although exchange strength quickly reduces as the NiCo-O thickness drops below 200 Å, the interaction between NiCo-O and NiFe still exists even for the thinnest samples in this work, evidenced by the higher coercivity present in the samples.

Preparation of soft magnetic Fe/Ta and Fe:N/Ta:N multilayered films with large magnetization for inductive recording head

Masahiko Naoe and Shigeki Nakagawa

Department of Physical Electronics, Tokyo Institute of Technology, 2-12-1 O-okayama, Meguro, Tokyo 152, Japan

Fe/Ta multilayered films were deposited on Si substrates by ion beam sputtering (IBS) by alternately using separate Fe and Ta targets. Thickness of Fe and Ta layers ℓ_{Fe} and ℓ_{Ta} bilayers $\ell_{\text{Fe}} + \ell_{\text{Ta}}$ in specimen films and total thickness of multilayers films with 10 bilayers were constant at 100 and 1000 Å, respectively. For as-deposited films, coercivity H_c took minimum value of 0.15 Oe at ℓ_{Fe} of 88 Å and ℓ_{Ta} of 12 Å, where saturation magnetization $4\pi M_s$ was 18.3 kG. Films postannealed at 500 °C exhibited $4\pi M_s$ of 19.1 kG, H_c of 0.05 Oe and μ_r of 1820. Fe:N/Ta:N multilayered films with N content of ~10 at. % were deposited by bombarding N ions extracted from the subgun while the films were being grown. For as-deposited films, H_c took minimum value of 0.07 Oe and μ_r took maximum value of 1310 at $\ell_{\text{Fe:N}}$ of 93 Å and $\ell_{\text{Ta:N}}$ of 7 Å, where $4\pi M_s$ was 20.5 kG. Films postannealed at 500 °C exhibited $4\pi M_s$ of 21.2 kG, H_c of 0.03 Oe and μ_r of 2380. Consequently, Fe/Ta and Fe:N/Ta:N multilayered films may be very suitable for magnetic cores in inductive heads for ultrahigh density recording. © 1996 American Institute of Physics. [S0021-8979(96)14708-X]

I. INTRODUCTION

It has been reported that the multilayered films, such as Fe/Al and Fe/Si multilayers, exhibit excellent soft magnetism.^{1,2} Inductive heads with high magnetic field for ultrahigh density recording need very soft magnetic thin films with sufficiently large saturation magnetization $4\pi M_s$ as magnetic cores in them. The Fe-Ta:N films postannealed at 500 °C exhibited $4\pi M_s$ of 19.7 and H_c of 0.05 Oe, respectively.³ Since Fe and Fe₈N exhibited $4\pi M_s$ as large as 21.4 and 29.0 kG,⁴ respectively, and Ta atoms are very insoluble into Fe layers, Fe/Ta multilayered films as well as Fe:N/Ta:N ones seemed to be hopeful for magnetic cores in the recording heads. Also, it is known that ion beam sputtering (IBS) is very useful in making multilayered films, since it can form continuous films with thickness as small as a few atomic layers. In this study, these multilayered films were deposited by using IBS apparatus and the relationship of their magnetic characteristics, the film construction and preparation condition was investigated.

II. EXPERIMENT

The dual ion beam sputtering (IBS) apparatus used in this study has a Kaufman-type of two guns with two grids. Ar and N₂ as pure as 99.999% at the pressure of 1.5×10^{-4} Torr was introduced through the main gun and subgun, respectively, as the working gas. Planar targets of Fe and Ta were sputtered by a uniform beam at an acceleration voltage for main gun and subgun of 500 and 100 V and extraction current of 3 and 1 mA, respectively. The deposition rates of Fe and Ta layers were ~15 and 10 Å/min, respectively.

At first, Fe/Ta multilayered films were deposited on Si wafers at room temperature by sputtering alternately with separate Fe and Ta targets. Thickness of Fe and Ta layers, ℓ_{Fe} and ℓ_{Ta} , respectively, were strictly controlled in the range between 0 and 100 Å. Thickness of Fe/Ta bilayers $\ell_{\text{Fe}} + \ell_{\text{Ta}}$ and total thickness of the multilayered films with 10 bilayers were set at constant values of about 100 and 1000 Å, respectively. Second, Fe:N/Ta:N multilayered films with

N content of ~10 at. % were deposited by bombarding N ions extracted from subgun on the surface of growing films by using the dual IBS apparatus. The postheating treatment for improving soft magnetic characteristics of the as-deposited films was carried out at the annealing temperature T_A of 500 °C for 1 h in vacuum at residual gas pressure below 2×10^{-6} Torr.

The saturation magnetization $4\pi M_s$ and the coercivity H_c were determined on M-H hysteresis loops measured by using a vibrating sample magnetometer. The relative permeability μ_r was determined by using a vector impedance meter at the frequency of 5 MHz.

III. RESULTS AND DISCUSSION

A. Saturation magnetization $4\pi M_s$

Figure 1 shows the dependence of $4\pi M_s$ on the thickness of Fe and Ta layers ℓ_{Fe} and ℓ_{Ta} , respectively, for the as-deposited and postannealed Fe/Ta multilayered films. The

FIG. 1. Dependence of saturation magnetization $4\pi M_s$ of Fe/Ta multilayer on layer thickness ℓ_{Fe} , ℓ_{Ta} .

FIG. 2. Dependence of saturation magnetization $4\pi M_s$ of Fe:N/Ta:N multilayer on layer thickness $l_{\text{Fe:N}}$, $l_{\text{Ta:N}}$.

saturation magnetization of both, as-deposited films and postannealed films, decreased from 20.1 to 0 kG nearly in proportion with the decrease of l_{Fe} and increase of l_{Ta} . The postannealed films exhibited significantly larger $4\pi M_s$ than the as-deposited ones for same l_{Fe} .

Figure 2 shows the dependence of $4\pi M_s$ on $l_{\text{Fe:N}}$ and $l_{\text{Ta:N}}$ for the Fe:N/Ta:N multilayered films. The saturation magnetization of the films decreased from 22.7 to 0 kG nearly in proportion with decrease of $l_{\text{Fe:N}}$ and $l_{\text{Ta:N}}$. The postannealed films exhibited apparently larger $4\pi M_s$ than the as-deposited ones for the same $l_{\text{Fe:N}}$ in the range of 40–80 Å. The as-deposited and postannealed Fe:N single layer films possessed larger $4\pi M_s$ of 22.5 and 22.7 kG, respectively, than that of bulk pure Fe (21.3 kG). It was found that the increase of $4\pi M_s$ after postannealing might be attributed to the increase in the size of Fe and Fe:N crystallites in the multilayers, since the value of crystallite size estimated by the half value width of x-ray diffraction peaks increased by a factor of 1.5–1.8 after postannealing.

B. Coercivity H_c

Figure 3 shows the dependence of H_c on l_{Fe} and l_{Ta} for the as-deposited and postannealed Fe/Ta multilayered films. H_c of both as-deposited and postannealed films decreased with increase of l_{Fe} in the range of 20–88 Å and increased with increase of l_{Fe} from 88 to 100 Å. The postannealed films exhibited remarkably lower H_c than the as-deposited ones for same l_{Fe} . H_c of the as-deposited and postannealed films took the minimum values of 0.15 and 0.05 Oe, respectively, at l_{Fe} of 88 Å.

Figure 4 shows the $l_{\text{Fe:N}}$ dependence of H_c for the Fe:N/Ta:N multilayered films. H_c of both films decreased with increase of $l_{\text{Fe:N}}$ in the range of 40–93 Å and increased with increase of $l_{\text{Fe:N}}$ from 93 to 100 Å. Also, the postannealed Fe:N/Ta:N multilayered films exhibited much lower H_c than the as-deposited ones for same $l_{\text{Fe:N}}$. H_c of the as-deposited and postannealed films took the minimum values of 0.07 and 0.03 Oe, respectively.

FIG. 3. Dependence of coercivity H_c of Fe/Ta multilayer on layer thickness l_{Fe} , l_{Ta} .

C. Relative permeability μ_r

Figure 5 shows the dependence of μ_r on l_{Fe} and l_{Ta} for the as-deposited and postannealed Fe/Ta multilayered films. μ_r of both as-deposited and postannealed films increased with increase of l_{Fe} in the range of 0–88 Å and decreased remarkably with increase of l_{Fe} from 88 to 100 Å. The postannealed films exhibited about two times higher μ_r than the as-deposited ones for same l_{Fe} . μ_r of the as-deposited and postannealed films took the maximum values of 1180 and 1820, respectively, at l_{Fe} of 88 Å.

Figure 6 shows the l_{Fe} dependence of μ_r for the Fe:N/Ta:N multilayered films. μ_r of both films increased drastically with increase of $l_{\text{Fe:N}}$ from 64 to 80 Å and decreased remarkably with increase of $l_{\text{Fe:N}}$ from 93 to 100 Å. Also, the postannealed Fe:N/Ta:N multilayered films exhibited about two times higher μ_r than the as-deposited one for same $l_{\text{Fe:N}}$. μ_r of the as-deposited and postannealed films took the maximum values of 1200 and 2380, respectively, at $l_{\text{Fe:N}}$ of 93 Å. The improvement of soft magnetism such as H_c de-

FIG. 4. Dependence of coercivity H_c of Fe:N/Ta:N multilayer on layer thickness $l_{\text{Fe:N}}$, $l_{\text{Ta:N}}$.

FIG. 5. Dependence of relative permeability μ_r of Fe/Ta multilayer on layer thickness l_{Fe} , l_{Ta} .

crease and μ_r increase seemed to be caused due to decrease in internal stress, since the degree in curvature of the specimens with very thin fused quartz substrates decreased drastically after postannealing.

IV. CONCLUSION

In this study, the Fe/Ta and Fe:N/Ta:N multilayers were deposited with the bilayer thickness of 100 Å and the total thickness of 1000 Å by using the dual ion beam sputtering apparatus. The relationship between their magnetic characteristics and the film construction and preparation condition was investigated. The obtained results are as follows:

(1) For the as-deposited Fe/Ta multilayers, the coercivity H_c took the minimum value of 0.15 Oe and the relative permeability μ_r took the maximum value of 1180, where the saturation magnetization $4\pi M_s$ was 18.3 kG.

FIG. 6. Dependence of relative permeability μ_r of Fe:N/Ta:N multilayer on layer thickness $l_{Fe:N}$, $l_{Ta:N}$.

(2) These Fe/Ta multilayers exhibited $4\pi M_s$ of 19.1 kG, H_c of 0.05 Oe, and μ_r of 1820, after postannealing at 500 °C.

(3) For the as-deposited Fe/Ta multilayers, H_c took the minimum value of 0.07 Oe and μ_r took the maximum value of 1310, where $4\pi M_s$ was 20.5 kG.

(4) This Fe:N/Ta:N exhibited $4\pi M_s$ of 21.2 kG, H_c of 0.03 Oe, and μ_r of 2380, after postannealing at 500 °C. Consequently, the Fe:N/Ta:N multilayers postannealed at proper temperature may be the most suitable for soft magnetic cores which are required to possess large $4\pi M_s$.

Cr(CoPtCr,CoPt)_x layered film studies for hard bias applications

A. Tsoukatos, S. Gupta, and D. Marx

Materials Research Corporation, 560 Route 303, Orangeburg, New York 10962

Cr(CoPtCr,CoPt) films were deposited on oxidized Si (100) substrates via dc magnetron sputtering. Process parameters, such as deposition rates, number of bilayers, and bias voltage, were varied to achieve the hard magnetic properties without thermal processing of the films. Coercivities in the range of 2000 Oe, with corresponding squareness of about 0.8–0.9, and remanent magnetization in the range (3–3.6) memu/cm², were achieved by identification of the optimum conditions. © 1996 American Institute of Physics. [S0021-8979(96)08908-6]

I. INTRODUCTION

CoPt-based alloys are well-established hard magnetic materials.^{1–4} However, the hard magnetic phase associated with these type of alloys is heat induced and the deposition processes for magnetoresistive head elements require ambient temperatures in the range of 100 °C. This range of temperatures is well below the range required for the precipitation of the CoPt face center tetragonal (fct) hard magnetic phase (i.e., >450 °C).⁵ Therefore, the development of hard magnetic films with CoPt-based alloys has been undertaken using process parameters, and adjacent metallic layers that can induce exchange coupling that results in hard magnetic behavior. The magnetic properties of these films may be improved by biasing the constituent underlayer, but this is a technique more appropriate for the development of media, for which the Cr underlayer is significantly thicker.⁶ The hard magnetic properties in correlation to the excellent oxidation resistance associated with these materials make them ideal candidates for media and MR head applications. The usefulness of the Cr(CoPtCr,CoPt) films for hard bias component in the former application is the focus of our experiments.

II. EXPERIMENTAL PROCEDURES

Cr(CoPtCr,CoPt) layered films were sputter deposited via dc rotating magnetron from 10 in. high-purity targets. The films were deposited on thermally oxidized silicon (100) 6 in. wafers. Deposition rates varied as a function of applied dc power (1–5 kW) and argon pressure (1–15 mTorr). The thickness of the Cr underlayer varied between 50 and 1000 Å, while the magnetic layer thicknesses ranged between 50 and 700 Å. Film samples (0.25 < A < 0.4 cm²) were subsequently evaluated in terms of their magnetic properties, using a vibrating sample magnetometer. The type of magnetic interactions present in these films were qualitatively studied via isothermal remanence curves, using a vibrating sample magnetometer.

The particular combinations of the Cr/magnetic layer structures studied were initially defined by an experimental design, which was used to statistically generate the range of process parameters, which were successively adjusted so as to achieve the optimum process. Additional experiments were performed using as a guide the bilayered structure (*n* = 1), which involved multilayered structures of (Cr/CoPtCr)_{*n*} with *n* > 1, and that resulted in achieving the desired mag-

netic properties while maintaining the total thickness within a comparable range to the bilayer.

In addition to the multilayered structures of rf biasing of the individual layers was successfully utilized to improve the magnetic properties of the bilayered structures.

The crystal structure of the films was determined via x-ray diffraction. Low-angle x-ray diffraction (XRD) was also used to quantify the integrity of the thinner layers deposited at higher deposition rates.

III. RESULTS AND DISCUSSION

In Table I the magnetic properties are shown with reference to the deposition rate (power) of the magnetic layer. The thickness of the magnetic component was found directly proportional to the resulting *M_rt* values. However, a more complicated interaction is involved in the thickness/deposition rate (power) effect on the coercivity of the magnetic component. Figure 1 shows a surface plot of the coercivity as a function of magnetic layer thickness and deposition power, as deposited at 3 mTorr, with a 200 Å Cr underlayer deposited at 3 mTorr and 5 kW.

The combined results of the above experiments have lead to the conclusion that, given the experimental conditions, it is difficult to maximize coercivity and magnetization simultaneously, at magnetic layer thicknesses below the 500 Å range, without rf biasing of the individual layers during deposition. Therefore, an alternative route was investigated that would allow simultaneous maximization of the magnetic features, with no significant changes of the process parameters but rather of the resulting film structure. The bilayer structure was changed to a (Cr/CoPtCr)_{*n*} structure with *n* = 2, 4, 10. A limitation was encountered in the number of *n*,

TABLE I. The effect of the magnetic layer deposition rates on the coercivity, squareness, and remanent magnetization per cm². The Cr underlayer was at 125 Å, and the deposition pressure was at 3 mTorr for the CoPtCr films, with the Cr at 150 Å and the deposition pressure at 5 mTorr for the CoPt films.

FIG. 1. Coercivity as a function of process conditions for a Cr/CoPtCr bilayer with constant Cr thickness at 200 Å.

since the overall structure thickness needs to be below the 1500 Å range in order to avoid excessive noise generation. The magnetic layer thicknesses used were at 50, 100, 250, 350, and 400 Å, while the underlayer was at 50, 100, 200, and 250 Å. Figure 2 shows the results for the $n=2$ structures (total structure thickness=1000–1300 Å). Although the combined thickness of the magnetic component became as high as 800 Å the resulting coercivity is of the order of 1900 Oe, with corresponding magnetic moment of 3.3 memu/cm². Furthermore, by reducing the underlayer thickness to 200 Å the coercivity of the structure is maintained in the 1800 Oe range while the value of the magnetic moment is 3.55 memu/cm².

The Rutherford Backscattering spectroscopy results for a $n=2$ structure are shown in Fig. 3. The effective layering of

FIG. 2. Magnetic properties of (Cr/CoPtCr)_n bilayers as a function of thickness of the Cr (CoPtCr, $t=400$ Å) and CoPtCr (Cr, $t=200$ Å) components.

FIG. 3. Rutherford backscattering spectra of a Cr/CoPtCr films for $n=2$.

the $n=2$ structure is clearly indicated by the two characteristic peaks for Pt ($Z=78$). Due to the proximity of the Z numbers for Co ($Z=28$) and Cr ($Z=24$), there is overlapping of their characteristic peaks, and, therefore, it is not possible to differentiate by visual observation. However, the least-squares techniques used to fit the spectrum quantifies the actual structure present. Figure 4 shows the low-angle x-ray diffraction spectrum of a Cr/CoPtCr multilayer with measured bilayer thickness of 152 ± 5 Å. The film structure was sputtered at high deposition power and the individual layer thicknesses were chosen so as to quantify the integrity of the layered structures at such deposition rates (Table I).

Similar high coercivity/high remanent magnetization combinations were also obtained by supplying rf bias to the substrate during the individual layer deposition. Figure 5 shows the plots of the magnetic data as a function of the layer thickness as deposited with rf bias conditions.

X-ray diffraction studies of these films provided limited information regarding the crystal structures present, due to

FIG. 4. Low-angle x-ray diffraction data for a [Cr-100/CoPtCr-50] multilayer with $n=10$.

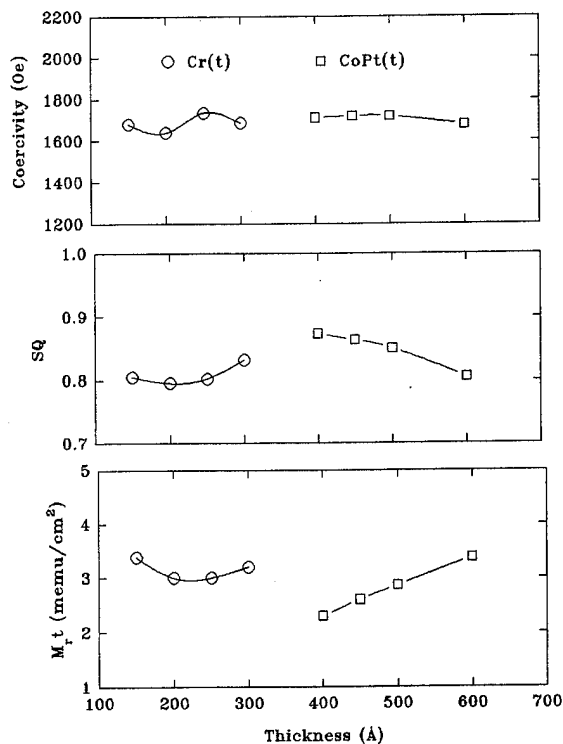

FIG. 5. Magnetic data for Cr/CoPt bilayers as deposited under the influence of substrate bias and as a function of layer thickness for each of the bilayer components.

the restricted resolution imposed by the films thicknesses. Figure 6 shows the spectrum of a Cr/CoPt film with total film thickness of about 850 Å. The characteristic (110) Cr line is present, although broadened due to the layer thickness (150 Å), with the two other peaks identified as components of the magnetic phase mixture consisting of CoPt₃, and Co [(111) fcc line]. However, more detailed crystal structure investigation is required via transmission electron microscopy (TEM), considering the film thicknesses in this study.

FIG. 6. X-ray diffraction spectrum for a Cr/CoPt film of total thickness of about 850 Å.

FIG. 7. ΔM curves indicative of positive interactions for Cr/CoPt bilayers as a function of (a) magnetic layer thickness, and (b) of Cr underlayer thickness.

The type of magnetic coupling present was identified via isothermal magnetic remanence curves. The concave down Henkel plots indicate positive interactions,⁷ which is in agreement with the results of the differentiated magnetizing and demagnetizing curves of these films that are indicative of positive exchange coupling. Figure 7(a) shows the ΔM curves for Cr/CoPt films at 150 Å Cr underlayer and varying magnetic layer thickness, with the corresponding ΔM curves as a function of underlayer thickness shown in 7(b), signifying the switching field strength relative to the film structure.

Ever since the pioneering work of C. G. Shull and E. O. Wollan in the early 1950s, neutron scattering has played a crucial role in expanding our understanding of magnetic materials. Neutrons have been the preferred tool to reveal the most detailed information on the magnetic structure and dynamics of the full range of materials exhibiting magnetic properties. Some highlights of the substantial body of work during the first 45 years of magnetic scattering will be presented. Topics include magnetic structures, magnetic form factors, magnetic phase transitions, and magnetic excitations. © 1996 American Institute of Physics. [S0021-8979(96)68308-X]

Neutron scattering as a probe of unconventional superconductivity in YBa₂Cu₃O₇ (invited) (abstract)

B. Keimer

Department of Physics, Princeton University, Princeton, New Jersey 08544

We have carried out a variety of neutron scattering experiments on the high temperature superconductor YBa₂Cu₃O₇ which elucidate the unconventional microscopic properties of the cuprates and illustrate the power and versatility of neutron scattering as a probe of novel materials. Small angle magnetic neutron diffraction is thus far the only technique capable of revealing the structure of the vortex lattice in the cuprate superconductors in magnetic fields of several tesla. We have shown that in YBa₂Cu₃O₇ the vortex lattice in this field range has an oblique structure when the field is applied along the *c* axis (perpendicular to the CuO₂ layers).¹ Recent theoretical work has attributed this unusual structure to the unconventional (*d*-wave) pairing state realized in the cuprates. We will also discuss the rich behavior of the vortex lattice when the field is tilted with respect to the *c* axis. We have used inelastic neutron scattering to elucidate the magnetic and lattice vibrational excitations in YBa₂Cu₃O₇. Magnetic and phonon scattering were separated both by detailed calculations of phonon dynamical structure factors and by neutron polarization analysis. A novel resonant magnetic excitation at wave vector $\mathbf{q}=(\pi/a,\pi/a)$ and energy $\hbar\omega=40$ meV appears in the superconducting state.² The simplest model for this resonance relies on quasiparticle pair creation and implies a sign reversal of the energy gap function on the Fermi surface. Alternative models will also be discussed. We have also observed a strongly wave vector dependent renormalization of the energy and lifetime of a specific phonon in the superconducting state of YBa₂Cu₃O₇.³ Since the phonon self-energy is sensitive to the anisotropies of the energy gap and Fermi surface via the electron-phonon interaction, our data contain important information about these parameters. © 1996 American Institute of Physics. Most magnets have long-range magnetic order when the thermal energy is less than the local magnetic exchange energy ($T < |\Theta_{\text{CW}}|$). Effects such as reduced dimensionality and frustration, however, can suppress the ordering transition and lead to unusual cooperative paramagnetic phases at low temperatures. We review neutron scattering experiments exploring such short-range-ordered phases in insulating transition metal oxides. We discuss $(\text{V}_{1-x}\text{Cr}_x)_2\text{O}_3$, in which orbital fluctuations appear to limit spin correlations to within small "molecular" clusters, $\text{SrCr}_9\text{Ga}_{12-9p}\text{O}_{19}$, in which geometrical frustration allows local antiferromagnetic constraints to be fulfilled without long-ranged order, and Y_2BaNiO_5 , in which magnetic interactions occur only within chains of spins which are unable to order because of the Haldane effect. Emphasis is placed on the common features of exchange interactions in these oxides and the important role which magnetic neutron scattering has played in understanding the unusual magnetic phenomena. © 1996 American Institute of Physics. [S0021-8979(96)72208-6]

I. INTRODUCTION

A common structural unit in magnetism is a transition series cation surrounded by six oxygen ions at the vertices of an octahedron.¹ This unit, for example, is the source of interacting magnetic moments in classical three-dimensional antiferromagnets such as MnO , FeO , CoO , NiO , Fe_2O_3 , and Cr_2O_3 . Adjoining octahedra, however, can also build periodic structures whose connectivity is not conducive to the development of conventional long-ranged order, and therefore may give rise to novel cooperative magnetic phenomena. In this article we review experiments examining such magnetic oxides which have strong magnetic fluctuations and short-ranged spin correlations even at low temperatures ($T \ll \Theta_{\text{CW}}$).

The neutron scattering techniques pioneered by Shull and Brockhouse are irreplaceable tools for elucidating spin correlations in these systems, much as they were for conventional Néel antiferromagnets.² The measured quantity is the probability that a neutron with a wave vector \mathbf{k}_i is scattered into a final state with wave vector \mathbf{k}_f through its interaction with the sample. Under suitable conditions this scattering process may be treated in the Born approximation, and in this case the scattering probability distribution is proportional to the neutron scattering cross section, which depends only on wave vector transfer, $\mathbf{Q} = \mathbf{k}_i - \mathbf{k}_f$, and energy transfer, $\hbar\omega = (\hbar^2/2m)(k_i^2 - k_f^2)$. Here we consider only the magnetic part of the scattering cross section, which is proportional to

$$I_m(\mathbf{Q}, \omega) = \sum_{\alpha\beta} (\delta_{\alpha\beta} - \hat{Q}_\alpha \hat{Q}_\beta) S^{\alpha\beta}(\mathbf{Q}, \omega), \quad (1)$$

where $S^{\alpha\beta}(\mathbf{Q}, \omega)$ is the dynamical spin correlation function,

$$S^{\alpha\beta}(\mathbf{Q}, \omega) = |F(\mathbf{Q})|^2 \frac{(g\mu_B)^2}{2\pi\hbar} \int dt e^{i\omega t} \times \frac{1}{N} \sum_{\mathbf{R}\mathbf{R}'} \langle S_{\mathbf{R}}^\alpha(t) S_{\mathbf{R}'}^\beta(0) \rangle e^{-i\mathbf{Q} \cdot (\mathbf{R} - \mathbf{R}')}, \quad (2)$$

which contains unique information about magnetic correlations in the sample. In this expression $F(\mathbf{Q})$ is the magnetic form factor, a property of the $3d$ orbitals.¹⁷

For powder samples the information available from magnetic neutron scattering is less specific than for single crystals, because the scattered intensity only depends on $Q = |\mathbf{k}_i - \mathbf{k}_f|$ and is proportional to the spherically averaged dynamic spin correlation function

$$\langle S(Q, \omega) \rangle = \int \frac{d\Omega}{4\pi} \hat{Q} \frac{1}{2} I_m(\mathbf{Q}, \omega). \quad (3)$$

Nonetheless, as we shall see, important results may still be extracted, especially in the small Q limit or when we are interested in Brillouin zone averaged quantities.

For comparison with bulk measurements, and between different neutron scattering experiments, we have in most cases measured scattering cross sections in absolute units. The scale factor between the detector count rate and the quantities of Eqs. (1)–(3) were determined by normalizing to count rates associated with known nuclear scattering cross sections of the samples.

II. ORBITAL FLUCTUATIONS IN $(\text{V}_{1-x}\text{Cr}_x)_2\text{O}_3$?

V_2O_3 can be insulating or metallic and antiferromagnetic or paramagnetic depending on temperature, pressure, and exact stoichiometry,³ and consequently the material has been a testing ground for theories of electronic correlations and

FIG. 1. Crystalline structure of $(V_{1-x}Cr_x)_2O_3$. The trivalent cations (filled circles) are surrounded by O^{2-} ions (open circles) on the vertices of trigonally distorted octahedra. (From Ref. 11.)

magnetism for decades.^{4,5} Here we shall confine our attention to the insulator $(V_{0.97}Cr_{0.03})_2O_3$ whose antiferromagnetism defies explanation in terms of a conventional Heisenberg spin Hamiltonian.

Figure 1 shows a sketch of the corundum structure of V_2O_3 . The trivalent cation sites, which are surrounded by six oxygen atoms on the vertices of trigonally distorted octahedra, form puckered honeycomb layers stacked in such a way that each vanadium site has a nearest neighbor above or below it. V^{3+} has only two $3d$ electrons which occupy the crystal field triplet t_{2g} . The t_{2g} orbitals have significant overlap only with their counterparts on neighboring vanadium atoms and this has two important consequences: (1) V_2O_3 is a Mott insulator as opposed to a charge transfer insulator. (2) Direct cation-cation overlap between in-plane nearest neighbors and the one out-of-plane nearest neighbor are the dominant sources of magnetic exchange interactions.¹ Even though these interactions would appear to yield a three-dimensional nonfrustrated antiferromagnet, the magnetic transition which takes place at $T_N=180$ K, is unusual because (1) it occurs far below $|\Theta_{CW}|=350$ K, (2) it involves an antiferromagnetic structure⁶ which is unique for corundum transition metal oxides^{2,7,8}, (3) it is accompanied by a lattice distortion, and (4) it is a first order transition.

To explore this unusual magnetic phase transition, we have examined spin correlations in the paramagnetic phase by inelastic magnetic neutron scattering. Figure 2 shows the wave vector dependence of neutron scattering at $T=205$ K and $\hbar\omega=3$ meV. For Q along the $(10l)$ direction we find two well-defined peaks which, in being almost as wide as the projection of the first Brillouin zone in that direction, imply that magnetic correlations involve only nearest neighbors. The data are qualitatively different from those derived from paramagnetic scattering in conventional three-dimensional

FIG. 2. Q dependence of inelastic scattering at $\hbar\omega=3$ meV and $T=205$ K in the paramagnetic insulating phase of $(V_{0.97}Cr_{0.03})_2O_3$. The 170 K data from the antiferromagnetic phase are a good measure of background and were subtracted from the 205 K data. The data were taken on BT2 at NIST with $E_f=13.7$ meV and collimations $60'-40'-40'-60'$ around the PG(002) monochromator and analyzer. A 1-in.-thick PG filter followed the sample.

antiferromagnets, not only because the correlations are so short ranged for $T/T_N-1=0.08$, but also because coherent scattering dominates over incoherent scattering despite the very short correlation lengths. Correlations are so short ranged, in fact, that we can fit the data to a truncated lattice sum which neglects all but the correlations between nearest neighbors,

$$S(Q) = \sum_{RR'} \langle S_R S_{R'} \rangle \exp[iQ \cdot (R - R')]. \quad (4)$$

The best fit, which also describes $(h,0,-5)$ and $(h01)$ scans at $\hbar\omega=3$ meV, is shown as a solid line in Fig. 2. From the fit we obtain values for nearest-neighbor spin correlations: $\langle S_{[0,0,0]} \cdot S_{(0,0,1/6+\delta)} \rangle = 0.6(3)$, $\langle S_{[0,0,0]} \cdot S_{(1/3,2/3,\delta)} \rangle = -0.19(8)$, $\langle S_{[0,0,0]} \cdot S_{(1/3,2/3,\delta-1/6)} \rangle = 0.18(8)$, and $\langle S_{[0,0,0]} \cdot S_{(1/3,2/3,1/6)} \rangle = -0.09(3)$ where $\delta=0.026$. These values were normalized so that $\langle S_{[0,0,0]} \cdot S_{[0,0,0]} \rangle = 1$. Figure 3 shows that it is not a lack of interactions that prevents longer-ranged correlations from developing. The full widths at half-maximum (FWHM) of constant- $\hbar\omega$ scans along the $(10l)$ direction through the peak at $Q \approx (101)$ are almost indistinguishable from those at $\hbar\omega=3$ meV, for energy transfers, $\hbar\omega$, as high as 18 meV. Also the nearly $\hbar\omega$ -independent peak amplitudes indicate that these correlations may persist to even higher energies.

The Q dependence of paramagnetic scattering from $(V_{1.97}Cr_{0.03})_2O_3$ resembles that of energy integrated scattering from isolated spin clusters in dilute magnets.⁹ However, the energy spectrum is continuous indicating that we are dealing with excitations in a macroscopic physical system. A possible explanation for this unusual behavior was recently proposed by Rice.¹⁰ His idea is that orbital fluctuations in the paramagnetic phase of $(V_{1-x}Cr_x)_2O_3$ inhibit long-ranged spin correlations through their effect on exchange interactions. In his description, which is based on the work of Castellani *et al.*,¹¹ one d electron is occupied in covalent bonding with the out-of-plane nearest neighbor while the other must choose which of the three in-plane vanadium neighbors to bond with. Pairs which bond have ferromagnetic spin-spin

FIG. 3. $\hbar\omega$ dependence of inelastic scattering for $Q \approx (101)$ at $T = 205$ K in $(V_{0.97}Cr_{0.03})_2O_3$ as derived from Lorentzian fits to constant $\hbar\omega$ scans along the $(10l)$ direction. The top frame is the amplitude of the modulated component, the middle frame is the FWHM, and the bottom frame is the peak position.

interaction whereas those which do not interact antiferromagnetically, and this leads to an effective spin-orbit coupling which cannot be accounted for by a conventional spin Hamiltonian. In this theory the coupling of the spin system to orbital fluctuations is what inhibits the development of spin order for $T \approx |\Theta_{CW}|$ and the magnetic transition is actually driven by an orbital ordering transition. In particular, the orbital order enables the development of long-ranged spin order by establishing an ordered array of spin exchange interactions. Further neutron scattering experiments probing the effects of orbital fluctuations on spin fluctuations both in the low and high temperature phases are underway to test this hypothesis.

III. ISOLATED SPIN PAIRS AND FRUSTRATION IN $SrCr_9pGa_{12-9p}O_{19}$

$SrCr_9pGa_{12-9p}O_{19}$ is a more complicated substance than most condensed matter physicists are normally willing to consider. Nonetheless, the unique magnetic properties of this insulating oxide do warrant attention. The bulk properties which called our attention to $SrCr_9pGa_{12-9p}O_{19}$ were (1) a magnetic susceptibility which follows Curie-Weiss behavior with $\Theta_{CW} = -500$ K down to $T \approx 100$ K,¹² (2) the absence of static order until a spin-glass-like transition at $T_g = 3.5$ K $\ll |\Theta_{CW}|$,¹³ and (3) low temperature specific heat data,

FIG. 4. Chromium ions (solid circles) and part of their distorted O^{2-} octahedral coordination in $SrCr_9pGa_{12-9p}O_{19}$. (From Ref. 16.)

$C(T)$, which in being proportional to T^2 resembles a long-range ordered two-dimensional magnet more than a conventional spin glass for which $C \propto T$.¹³

The aspects of the crystal structure which are relevant for this discussion are shown in Fig. 4. As in V_2O_3 , the trivalent magnetic cation, in this case Cr^{3+} , is surrounded by a distorted octahedron of oxygen atoms. The cation lattice is however more complicated in this case, encompassing three distinct sites which are denoted $12k$, $2a$, and $4f_{vi}$. The $12k$ layer is a slightly distorted Kagomé lattice whereas the $2a$ and $4f_{vi}$ layers are triangular lattices. The Cr^{3+} ions in the $12k$ - $2a$ - $12k$ block form corner-sharing tetrahedra, as in three-layer (111) slabs of the trivalent cation sites in the cubic pyrochlore^{14,15} and spinel structures.

Neutron scattering experiments have enabled us to derive a comprehensive model of magnetic interactions in this material, and to identify the three-layer $12k$ - $2a$ - $12k$ slab as the origin of the two-dimensional frustrated magnetism in $SrCr_9pGa_{12-9p}O_{19}$.¹⁶ Figure 5 shows wave vector integrated inelastic neutron scattering, $S(\omega)$, at $T = 1.3$ K from a powder sample of $SrCr_9pGa_{12-9p}O_{19}$ with $p = 0.92(5)$. Apart

FIG. 5. Energy dependence of wave-vector-integrated magnetic neutron scattering $S(\hbar\omega) = \int [I(Q, \omega)/F(Q)]^2 Q^2 dQ / \int Q^2 dQ$ from $SrCr_9pGa_{12-9p}O_{19}$, $p = 0.92(5)$ at $T = 1.3$ K. The data were obtained from 1139 μA h of beam time on the HET instrument at ISIS with $E_i = 100$ meV using slit pack C rotating at 100 Hz. The horizontal bars show the FWHM of the instrumental resolution. (From Ref. 16.)

FIG. 6. Q dependence of the integrated intensity of the 20 meV excitation in $\text{SrCr}_{9p}\text{Ga}_{12-9p}\text{O}_{19}$, $p=0.92(5)$ at $T=1.3$ K. The dashed line is the magnetic form factor squared for chromium (Ref. 17), the solid line was calculated for 0.7(1) antiferromagnetically interacting pairs of spins per formula unit. The inset identifies the 55 meV feature visible in Fig. 5 as a vibrational in origin because the integrated intensity rises with wave vector transfer. The data were obtained using the MARI instrument at ISIS (Ref. 16).

from the incoherent elastic peak and a broad spectrum of magnetic scattering visible from 0 to 40 meV, we notice a resolution limited peak at $\hbar\omega=18.6$ meV. Because the peak is sharp in wave-vector-integrated data, it must be associated with a nondispersive excitation and is therefore likely to arise from single atoms, or small clusters of atoms, which are decoupled from the rest of the system. From the Q dependence of the energy-integrated intensity of the ridge, shown in Fig. 6, we can exclude that it arises from (i) a local vibrational excitation, because the intensity decreases with Q and (ii) a crystal field excitation on a single chromium atom, because the Q dependence is distinguishable from the magnetic form factor for chromium.¹⁷ Instead, the Q dependence of the scattering closely resembles that from an isolated pair of antiferromagnetically interacting spins,⁹ shown as a solid line in Fig. 6. Such spin pairs also provide a detailed account for the energy and temperature dependence of the data, including a peak in $S(\omega)$ at $\hbar\omega=37.2$ meV which only appears for $T>100$ K.¹⁶

Considering also the values of the two fitting parameters which went into calculating the solid line in Fig. 6 and the position of the peak in Fig. 5, we conclude that there are 0.7(1) isolated spin pairs per formula unit in $\text{SrCr}_{9p}\text{Ga}_{12-9p}\text{O}_{19}$ [$p=0.92(5)$]. Spins of a pair are separated by $R\approx 2.68(7)$ Å and interact antiferromagnetically with an exchange coupling constant $J=18.6(1)$ meV. Since $4f_{vi}$ spins are the only spins which each are part of a unique spin pair, and since there are 0.78 $4f_{vi}$ - $4f_{vi}$ spin pairs per formula unit separated by 2.681(3) Å in our sample, it is likely that the $4f_{vi}$ Cr^{3+} ions are the ones forming isolated spin pairs in $\text{SrCr}_{9p}\text{Ga}_{12-9p}\text{O}_{19}$.

The oxygen octahedra of chromium ions in adjacent $4f_{vi}$ planes share a common face whereas the oxygen octahedra of neighboring $4f_{vi}$ and $12k$ sites share a corner. The exact same environment exists in corundum Cr_2O_3 where it has been established¹⁸ that the exchange constant between Cr^{3+} ions with corner sharing oxygen octahedra is only 0.2 meV

FIG. 7. Q dependence of elastic magnetic scattering from $\text{SrCr}_{9p}\text{Ga}_{12-9p}\text{O}_{19}$, $p=0.92(5)$ at $T=70$ mK. The data were obtained by subtracting elastic peak intensities at $T=20$ K from the same at $T=70$ mK. The experiment was performed on the IRIS instrument at ISIS using both its PG(002) analyzer (open circles) and its MICA(004) analyzer (open squares). (From Ref. 20.)

because occupied $3d$ orbitals in Cr^{3+} do not overlap oxygen orbitals.¹ Occupied orbitals of Cr^{3+} ions in face sharing octahedra, however, have appreciable direct overlap which in Cr_2O_3 gives rise to a 15 meV antiferromagnetic exchange coupling. This number, being close to the 18.6 meV exchange constant for spin pairs in SCGO [$p=0.92(5)$], supports our comparison to Cr_2O_3 and our conclusion that $4f_{vi}$ spin pairs form isolated singlets in $\text{SrCr}_{9p}\text{Ga}_{12-9p}\text{O}_{19}$.

Having accounted for the $4f_{vi}$ chromium sites we are left with the quasi-two-dimensional magnet consisting of a triangular lattice ($2a$) sandwiched between two Kagomé lattices ($12k$). Alternatively this lattice can be described as a three-layer (111) slab of the trivalent cation sites in the cubic pyrochlore or spinel structures. The oxygen octahedra of nearest neighbors within this spin system all share an edge and exchange interactions are therefore expected to be comparable in magnitude. Fitting high temperature bulk susceptibility data to the sum of the susceptibility of the $4f_{vi}$ spin pairs and a Curie-Weiss term to account for the pyrochlore slab, we extract a value of 9.5(5) meV for the average exchange constant within the slab. It is satisfying that this number is close to the value of 6.7(4) meV measured for the exchange constant between chromium ions whose octahedra share an edge in Cr_2O_3 .¹⁸

Evidently it is the reduced dimensionality and unique connectivity within this three-layer magnetic which give rise to the unusual cooperative magnetic properties of $\text{SrCr}_{9p}\text{Ga}_{12-9p}\text{O}_{19}$. We have performed a number of neutron scattering experiments to explore these properties.¹⁹ Our most interesting data are perhaps those establishing the Q dependence of elastic magnetic scattering in the spin glass phase.²⁰ The data, shown in Fig. 7, were obtained by subtracting elastic scattering at $T=20$ K $> T_g$ from the same at $T=70$ mK. Since the half-width at half-maximum (HWHM) of the energy resolution function in this experiment was 7.5 μeV (circles) and 2.25 μeV (squares) this measurement probes magnetic correlations which persist on the nanosecond time scale. From the wave vector integral of the data we

FIG. 8. Structure of Y_2BaNiO_5 . The oxygen ion which is a member of the octahedral coordination of two nickel ions mediates superexchange along the spin chain. (From Ref. 31.) Holes reside on this atom for $\text{Y}_{1.90}\text{Ca}_{0.10}\text{BaNiO}_5$.

conclude that the frozen moment in this system is only $1.9(2)\mu_B$, which is less than half of the frozen moment in a conventional Néel state formed by $S=3/2$ Cr^{3+} ions and thus implies that quantum spin fluctuations are strong in this insulating magnet. The elastic magnetic scattering is also unusual in that although we are dealing with a concentrated magnet with only weak structural disorder, there are no sharp peaks in the data, implying that long-ranged magnetic correlations are absent. Instead the broad peak at wave vector $Q \approx 1.5 \text{ \AA}^{-1}$ indicates the presence of short-range antiferromagnetic correlations. Since the width of the peak is comparable to its displacement from $Q=0$ static magnetic correlations are only maintained between nearest neighbors. Nonetheless, $S(Q)$ appears to vanish as $Q \rightarrow 0$. A vanishing forward cross section is very significant, because it implies that there exists a decomposition of the frozen spin state into subgroups of spins which possess net spin zero. The zero spin subgroups could be pairs, triangles, or tetrahedra of nearest-neighbor Cr^{3+} ions. Although such a spin configuration in principle could be concocted on most lattices, it appears to be the unique connectivity of the pyrochlore slab which makes such a spin configuration energetically favorable by allowing for all antiferromagnetic interactions to be satisfied without establishing long-ranged order. In this respect the frozen spin configuration in $\text{SrCr}_9\text{P}_{12-9p}\text{O}_{19}$ resembles the ground state of the weakly diluted classical Kagomé antiferromagnet which Shender *et al.*²¹ have found to obey a "rule of satisfied triangles."

IV. HALDANE GAP AND HOLE DOPING IN Y_2BaNiO_5

The combination of low dimensionality and a low integer spin quantum number ($S=1$) causes Y_2BaNiO_5 to be a rare example of a transition metal oxide which evades magnetic order down to temperatures as low as 50 mK.²² One dimensionality in this material comes about because oxygen octahedra, which coordinate Ni^{2+} , share a corner only for Ni^{2+} ions displaced along the a axis. Because Ni^{2+} ($3d^8$) has more than three $3d$ electrons, the superexchange interactions between such magnetic cations are strong,¹ and by dominating over all other exchange interactions, yield a one-dimensional antiferromagnet (see Fig. 8).

FIG. 9. Q dependence of inelastic magnetic scattering from a powder sample of Y_2BaNiO_5 at $T=10$ K for $\hbar\omega=6$ meV (open circles) and $\hbar\omega=9$ meV (filled circles). Background was measured for each of these scans at $\hbar\omega=-6$ and -9 meV, respectively, and subtracted. The horizontal bar corresponds to the FWHM Q resolution. The experiment was performed on the thermal neutron triple axis spectrometer BT2 at NIST with $E_i=40.3$ meV and collimations $60'-20'-42'-44'$ around the PG(002) monochromator and analyzer. A 2-in.-thick PG filter preceded the monochromator. (Adapted from Ref. 32.)

The consequences of this microscopic solid state chemistry for the magnetic properties of the material are quite astonishing. Figure 9, for example, shows the Q dependence of inelastic neutron scattering from a powder sample for $T=10$ K $\ll |\Theta_{\text{CW}}|$ K^{23} and $\hbar\omega=9$ meV $\ll k_B|\Theta_{\text{CW}}|$. In this low T and $\hbar\omega$ regime, neutron scattering from a conventional three-dimensional Heisenberg antiferromagnetic is strongest at low energies and always peaked for Q in the vicinity of magnetic Bragg peaks. For Y_2BaNiO_5 , however, inelastic scattering is only visible in the higher energy Q scan ($\hbar\omega=9$ meV) and only beyond a sharp onset at $Q=0.85 \text{ \AA}^{-1} \approx \pi/a$. Beyond this value no pronounced Q dependence is visible in the data except for a gradual decrease in intensity as Q increases. The absence of well-defined peaks in constant energy scans implies that long-ranged three-dimensional spin correlations do not exist in this material. However, the resolution limited onset of scattering as a function of Q distinguishes this magnet from conventional short-range ordered paramagnets, and indicates the presence of some form of long-ranged one-dimensional coherence.²⁴

The unusual absence of inelastic scattering at $\hbar\omega=6$ meV was further explored through a constant $Q=1.1 \text{ \AA}^{-1}$ scan (Fig. 10) which shows clear evidence of a 9 meV gap in the magnetic excitation spectrum. The single ion anisotropy of octahedrally coordinated Ni^{2+} cannot account for the gap, which instead appears to be an experimental example of the so-called Haldane gap²⁵ which characterizes the excitation spectrum of integer spin, one-dimensional antiferromagnets.^{26,27} It is interesting to note that this quantum many-body effect actually prevents magnetic order from taking place at any temperature in real materials such as Y_2BaNiO_5 and NENP²⁸ in which residual three-dimensional interactions do not exceed the threshold required to drive the gap to zero as they do in CsNiCl_3 .²⁶

What sets Y_2BaNiO_5 apart from other quasi-one-dimensional magnets previously studied is that holes may be

FIG. 10. $\hbar\omega$ dependence of inelastic neutron scattering at wave vector transfer $Q = 1.1 \text{ \AA}^{-1} = 0.65a^*$ and temperature, $T = 10 \text{ K}$. Solid circles are for Y_2BaNiO_5 , open triangles for $\text{Y}_{1.90}\text{Ca}_{0.10}\text{BaNiO}_5$, a material where holes are placed on the superexchange mediating oxygen ions with a mean separation of 10 nickel sites. The data were obtained on the thermal neutron triple axis spectrometer BT2 at NIST with $E_f = 14.7 \text{ meV}$ and collimations $60' - 20' - 42' - 44'$ around the PG(002) monochromator and analyzer. A 1-in.-thick PG filter followed the sample. The solid line is the background measured with analyzer turned 10° from reflection. The dashed line is the background resulting from $\lambda/2$ neutrons in the unfiltered incident beam. The dashed-dotted line shows the tails of the elastic signal superimposed on the previously mentioned background contributions. The sharp peak centered at $\hbar\omega = 0$ comes from incoherent elastic nuclear scattering. Adapted from (Ref. 29).

placed on the superexchange mediating oxygen atoms of the $(\text{NiO}_3)^{8-}$ chains by substituting Ca^{2+} for Y^{3+} .²⁹ This leads to a simple yet novel many-body system: Charge carriers interacting with a quantum spin liquid. The open triangles in Fig. 10 show that hole doping both introduces a subgap resonance in the excitation spectrum and shifts spectral weight above the gap to higher energies. Whereas the latter effect is also seen in samples where the average chain length is reduced by replacing Ni^{2+} by Zn^{2+} , the subgap resonance is peculiar to hole-doped samples. The simplest model which may be relevant for understanding the subgap resonance treats holes as static perturbations in the superexchange. In the analogous phonon problem a localized perturbation of interactions leads to a bound state or localized "optical" mode. A recent theoretical analysis of such a model has indeed identified a subgap resonance pinned to the middle of the Haldane gap when the impurity bond strength modulation exceeds a certain threshold.³⁰

High performance Nd₂Fe₁₄B-based permanent magnets are produced with different composition and various processing techniques. The composition and the processing route influence the complex, multiphase microstructure of the magnets, such as grain size, alignment, and distribution of phases. Grain sizes in the range between 10 and 500 nm are obtained by melt spinning, mechanical alloying, and the HDDR process. Sintered and hot worked magnets exhibit grain sizes above 1 μ m. The coercive field is determined by the high uniaxial magnetocrystalline anisotropy as well as the magnetostatic and exchange interactions between neighboring hard magnetic grains. The dipolar interactions between misaligned grains are more pronounced in large-grained magnets, whereas exchange coupling reduces the coercive field in small grained magnets. Transmission electron microscopy has been used to study the influence of substituent and dopant elements on microstructure, coercivity, and corrosion resistance of advanced (Nd,S1)-(Fe,S2)-B:(M1,M2) magnets. The replacement of the Nd-rich intergranular phase by secondary phases formed after doping by M1 and M2 type elements improves the corrosion resistance, especially in large-grained magnets. Secondary, nonmagnetic phases reduce the remanence and the energy product. In addition to the characterization of the microstructure, special attention has been paid to the computer modeling of the interaction between microstructure and coercivity. The simulation of the magnetization reversal process based on the real microstructure reveals a good agreement with experimental values. It is shown that the coercive field depends on grain size, distribution, and misorientation of grains. A strong exchange coupling between hard magnetic grains is desired in nanostructured magnets in order to improve the remanence. This effect is further increased by secondary, soft magnetic phases. Nanocrystalline, composite Nd-Fe-B based magnets show a remanence enhancement, both in experiments and in model calculations. © 1996 American Institute of Physics. [S0021-8979(96)38608-2]

I. INTRODUCTION

Different types of rare-earth permanent magnets, which show excellent hard magnetic properties, are based on SmCo₅, Sm₂Co₁₇, Nd₂Fe₁₄B, and Sm₂Fe₁₇N_x alloys with a high magnetocrystalline anisotropy of the hard magnetic phase.¹ Recent developments on iron-rare-earth magnets have been made in order to increase coercivity and corrosion resistance and to decrease material and production costs. Attempts are made to change the composition and to optimize the various preparation techniques, such as the powder metallurgical sintering process, the melt-spinning route, the mechanically alloying process and the hot working technique, in order to obtain Nd₂Fe₁₄B-based permanent magnets with high remanence, coercivity, and energy product. In addition to the primary hard magnetic phase, various secondary phases also occur, depending on the composition and the processing conditions. This is because of the complex phase relations and phase diagrams involved. The multicomponent composition of the magnets leads to the formation of nonmagnetic and soft magnetic phases. Generally, two types of substituent elements, which replace the rare-earth element or the transition element sites in the hard magnetic phase, and two types of dopant elements are distinguished.² Substituent

elements mainly change the intrinsic properties, such as spontaneous magnetic polarization, Curie temperature, and magnetocrystalline anisotropy.³ Depending on the type, the dopant elements, which show a low solubility within the hard magnetic phase, form additional intergranular rare-earth-containing or boride phases. These phases change the coupling behavior between the hard magnetic grains. Nonmagnetic intergranular phases eliminate the direct exchange interaction and also reduce the long-range magnetostatic coupling between the hard magnetic grains,⁴ both effects lead to an increase of the coercive field. On the other hand, the decrease of the volume fraction of the hard magnetic phases within the magnet decreases the remanence. Insufficient temperature stability and poor corrosion resistance are the main factors limiting applications of Nd₂Fe₁₄B-based magnets. Secondary nonmagnetic phases, which replace the Nd-rich intergranular phase, considerably improve the corrosion resistance and are of great technological interest.

The activities in permanent magnetism are mainly concentrated on the improvement of the magnetic energy density product, the corrosion resistance and the temperature coefficient of the coercive field of Nd-Fe-B-based magnets. The optimization of nitrided magnets, bonded magnets, and composite nanocrystalline magnets are prospective activities.⁵

The main emphasis of this paper is to distinguish different types of $\text{Nd}_2\text{Fe}_{14}\text{B}$ -based magnets and to show the influence of the microstructure on the coercivity.

II. MICROSTRUCTURE OF $(\text{Nd},\text{S1})-(\text{Fe},\text{S2})-\text{B}:(\text{M1},\text{M2})$ MAGNETS

$\text{Nd}-\text{Fe}-\text{B}$ -based permanent magnets exhibit a complex multiphase microstructure. According to the ternary phase diagram at least three equilibrium phases occur: the hard—magnetic $\text{Nd}_2\text{Fe}_{14}\text{B}$ phase (ϕ), the boride phase $\text{Nd}_{1+x}\text{Fe}_4\text{B}_4$, and the low melting Nd-rich phase (n). Other phases, such as Fe rich and Nd oxides, and pores are found depending on the composition and processing parameters.⁶ Selected substituent elements replace the Nd atoms ($\text{S1}=\text{Dy},\text{Tb}$) and the Fe atoms ($\text{S2}=\text{Co},\text{Ni},\text{Cr}$), respectively, in the hard magnetic ϕ phase and considerably change intrinsic properties, such as the spontaneous polarization, the Curie temperature, and the magnetocrystalline anisotropy. The formation of intermetallic, soft magnetic $\text{Nd}-(\text{Fe},\text{S2})$ phases, such as the Laves-type $\text{Nd}(\text{Fe},\text{S2})_2$ -phase,⁷⁻⁹ deteriorate the coercivity of the magnets. If dopant elements M1 or M2 are added to $\text{Nd}-\text{Fe}-\text{B}$, in some cases the coercivity is increased and the corrosion resistance is improved. Our previous, systematic transmission electron microscopy studies performed on sintered, melt spun, mechanically alloyed, and hot worked magnets have shown that two different types of dopants can be distinguished independently of the processing route. Both types influence the microstructure in a different way.¹⁰⁻¹⁵ (i) *Type 1 dopants* ($\text{M1}=\text{Al}, \text{Cu}, \text{Zn}, \text{Ga}, \text{Ge}, \text{Sn}$) \Rightarrow form binary $\text{M1}-\text{Nd}$ or ternary $\text{M1}-\text{Fe}-\text{Nd}$ phases, (ii) *Type 2 dopants* ($\text{M2}=\text{Ti}, \text{Zr}, \text{V}, \text{Mo}, \text{Nb}, \text{W}$) \Rightarrow form binary $\text{M2}-\text{B}$ or ternary $\text{M2}-\text{Fe}-\text{B}$ phases.

The main difference between substituent and dopant elements is the solubility range within the $\text{Nd}_2\text{Fe}_{14}\text{B}$ phase. The doping changes the microstructure of $\text{Nd}-\text{Fe}-\text{B}$ sintered magnets in the following way: If a solubility exists at the high temperature (1100 °C), the dopant element is partly dissolved in the hard magnetic $\text{Nd}_2\text{Fe}_{14}\text{B}$ phase (ϕ). This is the case for most of the M1-dopant elements (Al and Ga). The dopant element replaces the Fe atoms and therefore changes the spontaneous polarization, Curie temperature, and anisotropy field.³ If the solubility at sintering temperature is low, precipitation within the ϕ -phase occurs.¹⁶ This is mainly the case with M2 dopants. The main effect of the addition of dopant elements is the formation of new intergranular phases.²

In order to understand the formation of the microstructure and the enhancement of coercivity, various Dy- and Co-free $\text{Nd}-\text{Fe}-\text{B}$ magnets containing a combination of type 1 and type 2 additives, such as (Ga,Nb) ¹⁰ and (Cu,Nb) ,¹¹ were prepared by the conventional powder metallurgical route from hydrogen decrepitated (HD) powder and were investigated by means of transmission electron microscopy (TEM) after the magnetic characterization. In order to compare these results, we also studied the influence of the (Al,V) and (Al,Mo) additions on the microstructure of $\text{Nd}-(\text{Fe},\text{Co})-\text{B}$ and $(\text{Nd},\text{Dy})-(\text{Fe},\text{Co})-\text{B}$ magnets, respectively.

Type 1 dopants influence the wetting behavior of the liquid phase during the sintering or the hot working process

FIG. 1. TEM micrograph of the intergranular region between hard magnetic grains in the sintered $\text{Nd}_{15.5}\text{Fe}_{67.5}\text{Co}_5\text{B}_7\text{Al}_2\text{Mo}_3$ magnet showing the boride phase $(\text{Mo},\text{Fe})_3\text{B}_2$ (*iB*) and the Nd_3Co -phase (*iNc*).

and therefore affect the magnetic decoupling of the grains. After cooling from high temperature, the formation of additional Nd-containing intergranular phases like $\text{Nd}_6\text{Fe}_{13}\text{M1}_1$ [for $\text{M1}=\text{Al},\text{Ga},\text{Cu}$ (δ phase)], $\text{Nd}_3(\text{Ga},\text{Fe})+\text{Nd}_5(\text{Ga},\text{Fe})_3$, and NdCu or NdCu_2 occurs. The better separation and decoupling of the hard magnetic grains leads to the enhancement of the coercivity of the magnets. The replacement of the Nd-rich intergranular phase by new dopant-containing phases improves the corrosion resistance of the magnet. *Type 2 dopants* like V and Mo as well as W and Nb show a low solubility within the hard magnetic phase and form precipitates within the ϕ phase and intergranular borides, such as $(\text{V},\text{Fe})_3\text{B}_2$, $(\text{Mo},\text{Fe})_3\text{B}_2$, NbFeB , and WFeB . Ti and Zr doping lead to TiB_2 ¹⁷ and ZrB_2 precipitates, respectively. In $\text{Nd}-(\text{Fe},\text{Co})-\text{B}:\text{M1}$ -doped magnets the magnetic properties of the $\text{Nd}(\text{Fe},\text{Co},\text{M1})_2$ phases are changed and the coercivity is increased.¹⁸ In $\text{Nd}-(\text{Fe},\text{Co})-\text{B}:\text{M2}$ -doped magnets the formation of the soft magnetic $\text{Nd}(\text{Fe},\text{Co})_2$ phase is suppressed and the intergranular Nd-rich phase is partly replaced by the Nd_3Co phase. This main effect of this addition is to improve the coercivity and the corrosion resistance.

The TEM micrograph of Fig. 1 shows a typical two-phase intergranular region in the sintered $\text{Nd}_{15.5}\text{Fe}_{67.5}\text{Co}_5\text{B}_7\text{Al}_2\text{Mo}_3$ magnet. The Nd-rich phase is replaced by the Nd_3Co phase (*iNc*) and by the intergranular boride $(\text{Mo},\text{Fe})_3\text{B}_2$ (*iB*). In addition to these phases the $\text{Nd}_6\text{Fe}_{13}\text{Al}_1$ phase was also identified as an intergranular phase. A more detailed investigation of this magnet revealed the influence of the Al content on the coercivity and the formation of the Nd_3Co phase.¹⁹ A similar and comparable microstructure was previously observed by TEM investigations of the $\text{Nd}-(\text{Fe},\text{Co})-\text{B}:(\text{Al},\text{V})$ sintered magnet.¹⁵ Various additional phases were identified in the intergranular region in the sintered $\text{Nd}_{18}\text{Fe}_{74}\text{B}_6\text{Ga}_1\text{Nb}_1$ (Ref. 10) and $\text{Nd}_{15.4}\text{Fe}_{75.7}\text{Be}_{6.7}\text{Cu}_{1.3}\text{Nb}_{0.9}$ (Ref. 11) magnets, such as Ga- or Cu-containing Nd phases and Nb-containing boride phases. In accordance with the binary Ga-Nd phase diagram, the two phases were characterized as eutectoidal mixture of $\text{Nd}_3(\text{Ga},\text{Fe})$ and $\text{Nd}_5(\text{Ga},\text{Fe})_3$. A similar result was obtained in the $\text{Nd}_{15.4}\text{Fe}_{75.7}\text{B}_{6.7}\text{Cu}_{1.3}\text{Nb}_{0.9}$ magnet. Individual NbFeB

FIG. 2. Dependence of the coercive field on the sintering temperature and time of optimized $\text{Nd}_{15.1}\text{Fe}_{78.4}\text{B}_{6.1}\text{Ga}_{0.1}\text{Cu}_{0.3}$ magnets with high remanence (1.38 T) and energy density product (360 kJ/m³) (Ref. 20).

precipitates with diameters of less than 100 nm were identified within the grain interior of the ϕ phases of both magnets. Large NbFeB precipitates occur in the intergranular region between the hard magnetic grains. The combination of (Ga,Nb)- and (Cu,Nb)-doping shows both of types 1 and 2 microstructural changes. The advantage of the Nb addition is avoidance of the formation of α -Fe, which easily occurs in Ga- and Cu-doped magnets due to their phase relationship in the ternary phase diagram M1-Fe-Nd.

The processing route of the magnet strongly influences the grain size and grain size distribution. Optimized, sintered magnets with a maximum density exhibit an average grain size in the order of 5–10 μm . The coercive field strongly depends on the sintering parameters, such as temperature and time (Fig. 2).²⁰ Nanocrystalline and submicron magnets show a grain size in the range of 10–500 nm and are ob-

tained by the melt-spinning route,²¹ or by mechanically alloying,²² or by the HDDR (hydrogenation, disproportionation, desorption, and recombination) process.²³ TEM investigations of Nd-Fe-B ribbons show that the microstructure and the magnetic properties sensitively depend on the composition and the quench rate (wheel speed). The electron micrographs of Fig. 3 show the inhomogeneous grain size distribution from the free to the wheel surface side of the ribbon. For ribbons of the thickness of about 30 μm the average grain size of 20 nm near the wheel side increases to 500–700 nm near the free side. For low quenching rates different morphologies of the ϕ grains are observed. Preferential orientation of the grains is only found in equiaxed small grains and disappears for very large grains, as well as for dendritic structures. The most evident texture is observed in columnar grains which crystallized with the c -axis perpendicular to the ribbon plane.²⁴ The formation of intergranular phases between the hard magnetic $\text{Nd}_2\text{Fe}_{14}\text{B}$ grains is more pronounced in the large grained regions of the ribbon.²⁵ A magnetically anisotropic behavior has been found in HDDR processed, Co-substituted and Ga-, Zr-doped magnets.²⁶ The mechanism for the preferential orientation of $\text{Nd}_2(\text{Fe},\text{Co})_{14}\text{B}$ grains with an average diameter of about 300 nm after recombination is not yet clear. It is suggested that finely dispersed undecomposed $\text{Nd}_2(\text{Fe},\text{Co})_{14}\text{B}$ particles play an important role by acting as nuclei for the growth or recrystallization of the hard magnetic phase during the desorption process.²⁷ These particles can be formed under controlled hydrogenation conditions together with additives to decelerate the decomposition.

III. COERCIVITY

In $\text{Nd}_2\text{Fe}_{14}\text{B}$ based magnets, prepared by the sintering, the melt spinning, the mechanically alloying, or the hot working processing route the hard magnetic grains behave like single domain particles after magnetic saturation. The nucleation and the expansion of reversed magnetic domains control the coercive field during the magnetization reversal process. Micromagnetic calculations by Brown showed that the coercive field of an ideal, homogeneously magnetized material is given by the nucleation field expressed by²⁸

$$H_n = \frac{2K_1}{J_s} - (N_{\parallel} - N_{\perp}) \frac{J_s}{\mu_0} \quad (1)$$

where K_1 and J_s are the first anisotropy constant and the spontaneous magnetic polarization, respectively, and N_{\parallel} and N_{\perp} denote the demagnetization factors parallel and perpendicular to the rotational symmetry axis of an ellipsoidal particle.

Several authors have shown that the experimental results for the temperature dependence of the coercive field $H_c(T)$ of $\text{Nd}_2\text{Fe}_{14}\text{B}$ based magnets can be described independently by the processing route by the equation^{29–31}

$$H_c(T) = cH_A(T) - n \frac{J_s(T)}{\mu_0}, \quad (2)$$

where H_A is the anisotropy field, which is 5340 kA/m for $\text{Nd}_2\text{Fe}_{14}\text{B}$ at room temperature.³² The temperature indepen-

FIG. 3. Inhomogeneous grain size distribution across a $\text{Nd}_{15}\text{Fe}_{76}\text{B}_9$ ribbon. TEM micrograph taken (a) near free surface side and (b) wheel side.

dent constants c and n take into account the deteriorating effects of the real microstructure. A typical value of 0.2–0.5 was found for the parameter c , depending on the composition and processing parameters of the magnet. The parameter n (0.8–1.7) is related to the local demagnetizing field arising from free stray fields at internal phase and grain boundaries. The angular and the temperature dependence of H_c of sintered, melt spun and hot worked $\text{Nd}_2\text{Fe}_{14}\text{B}$ based magnets has been described by Givord and co-workers³³ by a different model. These authors consider that the magnetization reversal is initiated in a volume equal to the activation volume V_a determined from magnetic viscosity measurements. The coercive field is given by

$$H_c = c' \frac{\sigma_w}{V_a^{1/3} \mu_0 J_s} - n \frac{J_s}{\mu_0} - \frac{25kT}{\mu_0 J_s V_a}, \quad (3)$$

where σ_w is the domain wall energy and k is the Boltzmann constant.

A detailed micromagnetic treatment of the nucleation field was carried out by Kronmüller *et al.*^{34,35} and leads to the equation

$$H_n = \alpha_K \alpha_\psi \frac{2K_1}{J_s} - N_{\text{eff}} \frac{J_s}{\mu_0}, \quad (4)$$

where α_K describes the inhomogeneity of the magnetocrystalline anisotropy in grain boundary regions with anisotropy lower than that of the matrix phase and in which reverse domain nucleation is supposed to occur. α_ψ accounts for misaligned grains, and N_{eff} is an average effective local demagnetization factor. Experimental measurements³⁶ of the angular dependence of H_c of oriented sintered $\text{Nd}_2\text{Fe}_{14}\text{B}$ magnets showed that the factor α_ψ differs from the predictions of the Stoner–Wohlfarth theory³⁷ of noninteracting, single domain particles. MQI and MQII types of magnets show a similar magnetization reversal behavior and temperature dependence of H_c compared with sintered magnets.⁵⁵ A classical domain wall pinning behavior has not been found in such magnets. An increase of the magnetocrystalline anisotropy of the hard magnetic phase leads to an enhancement of the coercive field according to Eqs. (1), (2), and (4). Substituting Nd by Dy by a small amount considerably increases the anisotropy field and slightly decreases the spontaneous polarization.³⁵

A conventional, ideal, anisotropic Nd–Fe–B magnet consists of well-aligned grains which are completely separated by a nonmagnetic intergranular phase. Two conditions must be fulfilled for a complete surrounding of the hard magnetic grains. First, the dihedral angle,³⁹ which was found to be in the order to 10°–30° and decreases with the amount of doping,⁶ must become zero. Second, the volume fraction of the liquid phase during sintering must exceed a certain value ($\approx 20\%$). Both criteria are not fulfilled in Nd–Fe–B magnets. Thus, the typical microstructure consists of two types of grain boundaries, one containing intergranular phases especially at grain junctions and corners and one in direct contact to each other. Our studies are in good agreement with the theoretical consideration of the liquid phase sintering process.³⁹ The incomplete separation of the hard magnetic ϕ grains by a low-melting intergranular phase, lead to the fact that even in doped Nd–Fe–B magnets the ϕ grains are not

FIG. 4. Finite element calculation of the coercive field normalized by $2K_1/J_s$ as a function of the average misorientation angle of $\text{Nd}_2\text{Fe}_{14}\text{B}$ grains with different diameter (64 grains).

completely magnetically decoupled. These magnetic interactions therefore consist of long range *magnetostatic or dipolar interactions* and of the short range *exchange coupling* between misaligned grains. Both interactions determine the *coercivity* of $\text{Nd}_2\text{Fe}_{14}\text{B}$ -based magnets.⁴⁰ The contribution of exchange coupling between misaligned grains becomes more dominant with decreasing grain size.

IV. ROLE OF MICROSTRUCTURE ON COERCIVITY

Computer simulation of the magnetization reversal process has become an important tool for the investigation of microstructural effects on coercivity.^{41–44} The lack of the hysteresis models based on Eqs. (1)–(4) lies in the fact that they describe the behavior of angular and temperature dependence of the coercive field of magnets, but do not allow any predictions of the influence of a certain, real microstructure on the coercivity. Moreover, for a complete understanding of the influence of the microstructure on coercivity it is important to know the effect of microstructural parameters, such as grain size, shape of grains, misalignment of grains, etc., and of different distributions of these parameters on the coercive field. For the two- and three-dimensional, micromagnetic, finite element calculations a realistic grain structure was built by the assumption of different models of grain nucleation and growth.^{41,45} Corresponding to electron micrographs (Figs. 1 and 3) a real homogeneous or inhomogeneous distribution of phases and grain diameters was assumed for the calculations. The method of minimizing the total magnetic Gibbs free energy with respect to the magnetic polarization has been described previously.^{46,47} The creation of the microstructure starts with a random or preferential seeding for the nucleation of grains, followed by a uniform grain growth in all directions or a preferred growth in one direction, the triangulation of the grains for finite element calculation, and the distribution of hard, soft, and nonmagnetic grains. In our calculations, the total structure of 30–64 grains is divided into 20 000 meshes.

Figure 4 shows the calculated dependence of the coercive field as a function of the average misorientation of the hard magnetic $\text{Nd}_2\text{Fe}_{14}\text{B}$ grains. The deviation of the misalignment from the average value is in the order of $\pm 5^\circ$.

FIG. 5. Numerical calculation of the dependence of the nucleation field on the grain diameter of $\text{Nd}_2\text{Fe}_{14}\text{B}$ magnets.

Similar results are obtained for small (50 nm) and large (5 μm) grained magnets. The upper limit for the coercive field of a real magnet with about 20° misorientation is only 1/3 of the maximum theoretical value of the anisotropy field. From theoretical considerations it is obvious that an improvement of the alignment by changing the processing steps increases both the remanence and coercive field.⁴⁸ The dependence of the nucleation field on the average grain diameter is shown in Fig. 5. The nucleation field is defined at the field H_n ($|H_n| \leq |H_c|$) at which irreversible magnetization reversal processes first occur after saturation. The nucleation field increases with decreasing grain diameter. This observation corresponds to coercive fields obtained after varying sintering temperatures and times (Fig. 2). The calculations predict that in an isotropic mechanically alloyed or melt-spun magnet the maximum coercive field is obtained for a mean grain diameters of 20 nm. The effect of an inhomogeneous distribution of grains with different diameter, simulating the case of the cross section of a melt-spun ribbon with different grain sizes at the wheel and free surface side (Fig. 3) is shown in Fig. 6. The demagnetization curve of the inhomogeneous microstructure shows a lower coercive field compared to the homogeneous one (Fig. 7). The current and previous numerical micromagnetic calculations reveal that the interplay of the magnetostatic and exchange interactions between neighboring grains limit the coercive field considerably. Nanocrystalline, single phase Nd-Fe-B magnets with isotropic alignment show an enhancement of remanence. Soft magnetic grains in composite permanent magnets cause a high polarization, and hard magnetic grains induce a large coercive field provided that the particles are small and strongly exchange coupled.⁴⁹⁻⁵³ Micromagnetic calculations, which were obtained for a composite material of nanocrystalline SmCo_5 , $\text{Nd}_2\text{Fe}_{14}\text{B}$, and $\text{Sm}_2\text{Fe}_{17}\text{N}_{2.7}$ grains, and $\alpha\text{-Fe}$ as soft magnetic phase, show that remanence, coercivity, and coercive squareness sensitively depend on microstructural features, such as the grain size and the volume fraction of the soft magnetic phase.^{47,54} Interparticle exchange interactions enhance the remanence by about 60% with respect to noninteracting particles for a mean grain size of 10–20 nm. The

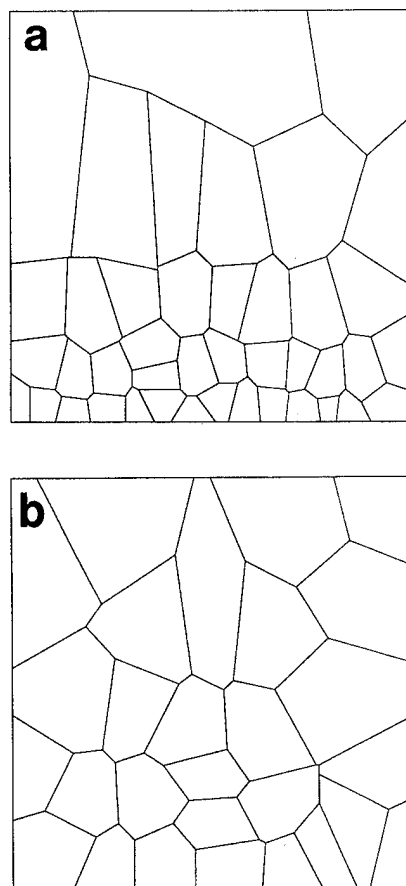

FIG. 6. Computer generated microstructure of $\text{Nd}_2\text{Fe}_{14}\text{B}$ melt spun ribbons with inhomogeneous grain size distribution. The grain sizes range from (a) 17 to 146 nm and from (b) 40 to 114 nm (Ref. 45).

remanence enhancement and energy product increases with decreasing grain size and increases with increasing $\alpha\text{-Fe}$ content. Because of their remarkably high magnetocrystalline anisotropy, novel nitrided intermetallic compounds have a large potential for composite permanent magnets.

V. CONCLUSIONS

Rare earth permanent magnets exhibit a complex, multi-phase microstructure, which considerably influences the coercivity and the remanence of the magnets. $\text{Nd}_2\text{Fe}_{14}\text{B}$ based hard magnets can be distinguished by different processing routes, by microstructural differences, or by the kind of elemental substitution or addition. There exist metallurgical reasons for long range dipolar interaction and short range exchange coupling between neighboring hard magnetic grains. The doping of elements changes the phase relation and favors the formation of new phases. Additional secondary nonmagnetic intergranular phases decrease the remanence and interrupt the magnetic interactions between the grains, thereby improving the coercivity of large grained sintered or hot worked magnets. Soft magnetic secondary phases, such as $\alpha\text{-Fe}$, destroy coercivity in large grained magnets. The additional intergranular phases partly replace the Nd-rich phase and considerably improve the corrosion resistance of the magnet. Numerical, micromagnetic calculations have shown that microstructural parameters, such as

FIG. 7. Calculated demagnetization curves of the inhomogeneous microstructure of Fig. 6(a) and of the homogeneous microstructure of Fig. 6(b).

grain size, misorientation, and distribution of grains and phases control coercive field. The dipolar interactions considerably reduce the coercive field of ideally oriented particles by about 20% with respect to H_c of an isolated particle, and exchange coupling between misaligned grains drastically reduces the coercive field to about 30%–40% of the ideal nucleation field. Contrary to the situation found in large-grained magnets, the strong coupling between the hard magnetic grains is desired in nanostructured, composite rare earth permanent magnets. The excellent hard magnetic properties of isotropically oriented grains are attributed to inter-grain exchange interactions, which enhance the remanence by more than 40% as compared to the remanence of noninteracting particles, if the grain size is in the order of 10–30 nm. The content of soft magnetic phases up to 20% is favorable for increased remanence enhancement and sufficient high coercive fields. The advantage of the nitrided $\text{Sm}_2\text{Fe}_{17}$, compared to $\text{Nd}_2\text{Fe}_{14}\text{B}$, is the better temperature stability of the permanent magnetic properties.

High performance NdFeB magnets (invited)

A. S. Kim and F. E. Camp

Crucible Research Center, A Division of Crucible Materials Corporation, 6003 Campbells Run Road, Pittsburgh, Pennsylvania 15205-1022

Although the production and applications of NdFeB magnets have increased enormously in the last decade because of their outstanding magnetic properties at room temperature, some applications were limited because of poor thermal stability and corrosion resistance. To address these problems, there have been many efforts and much progress. In many instances, the alloy modifications produced an improvement of some characteristics but only at the expense of other characteristics. It is therefore necessary to find a method (or alloy) for improving the thermal stability, coercivity, and corrosion resistance without sacrificing performance. We have found that the proper control of very small amounts of Cu, Co, and O in (Nd, Dy)FeB alloys substantially improves the coercivity, high-temperature capabilities, and corrosion resistance without a reduction of remanence. As a result, a high performance NdFeB magnet with excellent temperature stability and corrosion resistance was developed. © 1996 American Institute of Physics. [S0021-8979(96)38708-1]

I. INTRODUCTION

NdFeB magnets were discovered in 1983 with outstanding magnetic properties at room temperature.^{1,2} In the initial stage of development, the maximum energy product of sintered NdFeB magnets was close to 30 MGOe.¹ Since then, this value has become considerably improved. In 1985, Narashimhan³ reported 45 MGOe and in 1993 Kaneko *et al.*⁴ reported 54.2 MGOe. The maximum energy product commercially available today is about 45 MGOe. Because of this high energy product, applications have increased enormously in the last decade. Current applications include consumer electronics, computer peripherals, acoustics, office automation, and magnetic resonance image. However, some applications were limited because of poor thermal stability (low T_c and high-temperature coefficient of B_r and H_{ci}) and corrosion resistance. To address this problem, there have been many efforts and much progress. In many instances, the alloy modifications produced an improvement of some characteristics but only at a cost of impairing other characteristics.

For example, the addition of cobalt^{5,6} to Nd(Dy)FeB increases the Curie temperature and reduces the temperature coefficient of residual magnetization (B_r), but because the coercivity is decreased by its addition, the temperature stability is not actually improved. To overcome cobalt's negative effect and to enhance the coercivity, various elements have been added to NdFeB. Substitution of Nd by heavy rare earth (HRE) elements⁶ such as Dy or Tb increases the anisotropy and thus increases the coercivity. However, these HREs decrease the saturation magnetization and thus reduce the remanence and energy products.

The addition of grain boundary modifying elements⁷⁻⁹ such as Al, Ga, and Sn was also found to effectively increase the coercivity. The effect of the additives in the intergranular phase is to form nonmagnetic compounds that can magnetically isolate the grains of the main phase during sintering. However, most additives have the unfavorable property of decreasing the magnetization of the main phase, and thus reduce the remanence and energy products.

Refractory elements¹⁰⁻¹² such as Nb, Mo, V, W, Cr, Zr, Ti, etc., were also found to enhance the coercivity. Those

additives suppress the formation of α -Fe to some extent, inhibit grain growth during sintering and may form borides in the grain boundary and/or within the main $\text{Nd}_2\text{Fe}_{14}\text{B}$ phase. By forming nonmagnetic phases, they largely reduce the remanence and energy products.

Since the addition of alloying elements such as those described above usually accompanies unfavorable decreases of remanence and energy product, the increase in coercivity (or improvement in temperature stability) was traded off at the expense of magnetic performance. Therefore, it is necessary to find a method (or alloy) for improving the thermal stability (T_c and/or H_{ci}) without such reduction.

Because the remanence and energy product are reduced by (1) the reduction of M_s value of the $\text{Nd}_2\text{Fe}_{14}\text{B}$ phase with the addition of heavy rare earth elements such as Dy or Tb, or of grain boundary modifiers such as Al, Ga, or Sn, (2) the formation of a nonmagnetic boride phase such as $(\text{M}, \text{Fe})_3\text{B}_2$ with refractory elements such as those described above, it is necessary to design a microstructure having only nonmagnetic grain boundaries without such B_r reducing factors for enhancing coercivity. It is also necessary to increase the T_c of the $\text{Nd}_2\text{Fe}_{14}\text{B}$ phase without changing the M_s and H_A values in order to improve the temperature stability. If we design such a magnet based on this assumption, it will have higher T_c and H_{ci} without B_r reduction.

For improving the corrosion resistance, it is necessary to change the Nd-rich grain boundary from a reactive to a non-reactive phase. Adding Co^{13,14} to this alloy changes the grain boundary phase from Nd-rich (Nd-Fe) to a Nd_3Co or $\text{Nd}(\text{Fe}, \text{Co})_2$ phase. These additions improve the corrosion resistance but at the expense of coercivity. Therefore, it is necessary to change this Co-containing ferromagnetic grain boundary phase to a nonmagnetic phase in order to enhance the coercivity as well as the corrosion resistance.

Based on this design, we attempted to develop an alloy which improves not only the thermal stability (T_c and H_{ci}) and corrosion resistance but also the magnetic performance (B_r and BH_{max}).

FIG. 1. Demagnetization curves of (Nd,Dy)FeB magnets with and without Cu addition.

II. EXPERIMENTAL PROCEDURE

The R-(Fe,Co)-B magnets used in this study were prepared by the conventional powder metallurgy process. The material was produced by vacuum introduction melting of a prealloyed charge of high purity elements and master alloys to produce a molten mass of the desired alloy composition. The molten mass was poured into a cooper book mold or atomized into fine powders with argon gas. The case ingot or atomized powder was hydrided at 1–30 atm. The cast ingot was crushed and pulverized into coarse powders. The pulverized powder or atomized powder was then ground into fine powders by jet milling with an inert gas such as Ar or N₂ gas. The average particle size of the milled powders was in the range of 1–5 μ m by Fisher subsieve sizer measurements.

The prepared powders were placed in a rubber bag, aligned in a magnetic field, and compacted by cold isostatic pressing. The pressed compacts were then sintered to approximately their theoretical density in a vacuum furnace at between 900 and 1100 °C for 1–4 h. The sintered magnets were further heat treated at about 800–900 °C for 1 h and

FIG. 2. Effect of Cu content on the coercivity of 30.5Nd–2.5Dy–bal (Fe,Co)–1.1B alloy.

FIG. 3. Demagnetization curves of 30.5Nd–2.5Dy–1.1B–1.2Co–bal Fe magnets with and without Cu addition.

then aged at between 450 and 700 °C. The magnets were ground and sliced into cylindrical shapes (6 mm thick×15 mm diam).

The magnetic properties of the ground magnets were measured with a hysteresigraph equipped with a high-temperature search coil. The irreversible loss was estimated by measuring the flux difference with a Helmholtz coil before and after exposing the magnet at elevated temperatures (up to 250 °C) for 1 h. The permeance coefficient was one. The oxygen content of the sintered magnet was analyzed by a Leco oxygen analyzer (Model No. TC436AR).

The corrosion rate was determined by measuring the weight loss after exposing the magnets to an autoclave at 110–115 °C and at 10–15 psi steam pressure for 96 h.

III. RESULTS AND DISCUSSION

A. Effect of minor elements such as Cu and Co

It was found that the coercivity of a (Nd,Dy)FeB magnet was substantially increased by very small additions of copper (as low as 0.03% Cu) as shown by the demagnetization curves in Fig. 1. Therefore, we investigated the effect of copper variation on the magnetic properties of (Nd,Dy)FeB and (Nd,Dy)(Fe,Co)B alloys.

FIG. 4. Irreversible losses of 30.5Nd–2.5Dy–1.1B–bal (Fe,Co,Cu) magnets as a function of Cu and Co content.

TABLE I. Corrosion rates (wt. losses) of 33Nd-1.1B-XCo-YCu-bal Fe magnets after autoclave tests at 110-115 °C for 96 h.

% Co	% Cu	Wt. loss (mg/cm ²)
0	0	203.3
5.0	0	17.5
0	0.15	18.3
1.2	0.15	0.15

Figure 2 shows the H_{ci} variations as a function of copper content in (Nd,Dy)FeB and (Nd,Dy)(Fe,Co)B alloys. The coercivity of the (Nd,Dy)FeB alloy rapidly increases up to 0.005% Cu, reaches a maximum of 0.02% Cu, and then remains the same with further increases in copper content up to 0.12%. Therefore, a very small amount (as low as 0.005%) of copper is sufficient to increase the coercivity of (Nd,Dy)FeB alloys. On the other hand, the coercivity of the (Nd,Dy)(Fe,Co)B alloy continuously rapidly increases up to 0.1% Cu, slowly reaches a maximum at 0.2% Cu, and then starts to slowly decrease with further increases in copper content. The degree of coercivity increase in the (Nd,Dy)(Fe,Co)B alloy is much larger than that in the (Nd,Dy)FeB alloy. The average remanence remains the same up to 0.2% Cu in the (Nd,Dy)(Fe,Co)B alloy. Since Co additions increase the T_c without changing the M_s and H_A values, the combined additions of Co and Cu increase not only H_{ci} but also T_c without reducing B_r .

Figure 3 compares demagnetization curves of identical 30.5Nd-2.5Dy-1.2Co-1.1B-bal Fe magnets with 0% and 0.15% copper addition. The coercivity is substantially increased (~6 kOe) with a small addition (0.15%) of copper while the remanence slightly increases. This may be due to

FIG. 5. Variation of H_{ci} for 29Nd-4Dy-bal Fe-5Co-1.15B-M alloys, as a function of oxygen content.

FIG. 6. Demagnetization curves of 30.5Nd-2.5Dy-1.2Co-1.1B-63.4Fe magnets with and without oxygen doping.

grain boundary modification without affecting the matrix phase. Because the very small additions of copper do not sacrifice either the remanence or Curie temperature, they can overcome the negative effect of cobalt in NdFeB magnets and further enhance the coercivity.

Because of the dramatic increase in coercivity by the combined addition of cobalt and copper in (Nd,Dy)FeB alloys, the temperature stability is also substantially improved. As shown in Fig. 4, the irreversible loss of a 30.5Nd-2.5Dy-1.1B-bal Fe magnet is not changed by the addition of cobalt, is reduced by the very small addition of copper (0.02%), and is substantially reduced by the combined addition of cobalt and copper. The magnet operating temperature has increased by about 25 °C for the single addition of copper and by about 75 °C for the combined addition copper and cobalt. Therefore, the temperature stability of (Nd,Dy)FeB can be significantly improved without B_r reduction by small additions of Co and Cu.

The corrosion resistance of a (Nd,Dy)FeB magnet is also improved by the combined addition of Co and Cu. As shown in Table I, the weight loss from autoclave testing is substan-

FIG. 7. Comparison of irreversible losses ($PC = 1.0$) of 28Nd-6Dy-1.1B-2.5Co-0.15Cu-bal Fe magnets with and without oxygen doping.

tially (about one magnitude) reduced by the addition of either Cu or Co. When Cu and Co are added together, the weight loss approaches zero. This indicates that the corrosion resistance is also significantly better by the combined addition of Cu and Co than from any single addition. Therefore, improved corrosion resistance of NdFeB magnets can be obtained without sacrificing magnetic performance by the very small additions of cobalt and copper.

B. Effect of oxygen

Since oxygen is inevitably introduced into the sintered NdFeB magnets during the process, it is necessary to systematically determine the effect of oxygen on the magnetic properties and to define the proper content range. We examined the magnetic properties of (Nd,Dy)(Fe,Co)B alloys containing various levels of oxygen.

As shown in Fig. 5, the coercivity of a cobalt containing (Nd,Dy)(Fe,Co)B magnet initially increases rapidly with increasing oxygen content up to about 0.4% and then starts to decrease with further increases in oxygen content. The optimum oxygen content for the peak coercivity varies depending on the total rare earth content and other minor phases. We made magnets from the same (Nd,Dy)(Fe,Co)B alloy with and without oxygen doping, and compared their magnetic properties. As shown in Fig. 6, both B_r and H_{ci} are increased by oxygen doping. The coercivity improvement will be discussed under microstructural analysis.

Since the coercivity of a (Nd,Dy)(Fe,Co)B alloy is improved by proper oxygen doping, we compared the irreversible losses of the same 28Nd-6Dy-1.1B-2.5Co-0.15Cu-bal Fe with and without oxygen doping. As shown in Fig. 7, the irreversible loss is greatly improved by oxygen doping, where the operating temperature of the higher oxygen magnet is increased by as much as 50 °C.

We also measured the magnetic properties of both magnets at 20 and 150 °C and compared the temperature coefficients as shown in Table II. With oxygen doping the remanences are slightly increased at both temperature levels. The coercivities at 20 and 150 °C are substantially increased with oxygen doping. The temperature coefficient of coercivity has improved from -0.51%/°C to -0.44%/°C. Since the temperature coefficient of the same alloy without Co and Cu is about -0.65%/°C, the temperature coefficient of H_{ci} was substantially improved by the combined addition of Co and Cu, and further improved by oxygen doping.

FIG. 8. SEM micrograph of 28Nd-6Dy-1.1B-2.5Co-0.15Cu-bal Fe magnet.

Thus, the temperature stability and corrosion resistance of (Nd,Dy)(Fe,Co)B magnets can be substantially improved, without a reduction of remanence, by the combined addition of cobalt and copper. A proper oxygen doping of this alloy system further improves the temperature stability without B_r reduction (or with improved remanence).

C. Microstructural study

A magnet made from a (Nd,Dy)(Fe,Co,Cu)B alloy was examined in a SEM with EDS. As shown in Fig. 8, the microstructure reveals a grey (matrix) phase and a white (Nd-rich) grain boundary phase without discernable other (boride) phases. The EDS spectra on the white phase identifies it as mainly (Nd,Dy)₁₅Co₄Cu. These results indicate that the addition of small amounts of Cu and Co to (Nd,Dy)FeB alloys modifies the grain boundary phase from Nd-rich (Nd-Fe) to (Nd,Dy)₁₅Co₄Cu without forming any nonmagnetic grains or changing the matrix phase. This fulfills the requirements of microstructural design suggested in the Introduction. The (Nd,Dy)₁₅Co₄Cu phase, which is being further investigated, is assumed to be nonmagnetic because the coercivity is dramatically enhanced.

The effect of oxygen doping of the (Nd,Dy)(Fe,Co)B magnet on the microstructure was examined in a TEM. The TEM micrographs of magnets with and without oxygen doping exhibit an equiaxed grain structure as shown in Fig. 9. The grains in the magnet without oxygen doping appear to be uniformly decorated with a 50 nm thick intergranular phase. There are numerous defects. In the magnet with oxygen doping, the grain size becomes finer, and the intergranular phase appears to be largely confined to the triple junctions. The grain boundaries in this sample are very smooth without apparent defects, leading to better coercivity. As reported by Choi *et al.*,¹⁴ the reduction of Laves phase Nd(Fe,Co)₂ in the grain boundary from oxygen doping may also contribute to the increase in coercivity, because Co additions to the (Nd,Dy)FeB alloy usually forms the magnetically soft Laves phase which reduces the coercivity.

FIG. 9. TEM micrograph of 30.5Nd–2.5Dy–1.1B–1.2Co–0.15Cu–bal Fe magnets with (b) and without (a) oxygen doping.

IV. CONCLUSION

The very small addition of copper (as low as 50 ppm) to (Nd,Dy)FeB alloys has substantially increased the coercivity without reducing B_r . The combined small addition of copper and cobalt to these alloys dramatically increased the coercivity without B_r reduction. This may be due to the formation of nonmagnetic grain boundary phases without forming nonmagnetic grains or without decreasing saturation magnetization. The proper amount of oxygen doping in these (Co and Cu containing) alloys further increases the coercivity with a slight increase in remanence. This may be due to grain growth inhibition, grain boundary cleaning, and/or grain orientation enhancement. Such additions also substantially reduce both temperature coefficient of coercivity and the irreversible temperature loss. Because of the increased

coercivity and reduced temperature coefficient of coercivity, the temperature stability has improved enormously without a sacrifice of (or with improved) magnetic performance. The combined small additions of copper, cobalt, and oxygen have also improved the corrosion resistance. Therefore, a high performance, temperature stable, and corrosion resistant magnet is developed by the combined small addition of Co, Cu, and O to (Nd,Dy)FeB alloys.

Anisotropic Nd-Fe-B bonded magnets made from HDDR powders (invited)

T. Takeshita and K. Morimoto

Materials Research Laboratories, Central Research Institute, Mitsubishi Materials Corporation,
1-297, Kitabukuro-cho, Omiya, Saitama 330, Japan

Anisotropic Nd-Fe-B magnet powders can be produced by the hydrogenation-decomposition-desorption-recombination (HDDR) process from Nd-Fe-B-Co-M ($M = \text{Ga, Zr, Nb, Hf, and Ta}$) alloys. The present status of those HDDR powders and the bonded magnets made from them are reviewed with regards to the powder particle size dependence of their magnetic properties, their magnetic thermal stability, and their magnetization behavior. The results of a mechanistic study on the recombination step are also presented. The magnetic properties of the anisotropic HDDR powder depend relatively little on the powder particle size. Bonded magnets with a density of $\sim 6.20 \text{ g/cm}^3$ and a BH_{max} of 18.5–20.5 MGOe can be produced from anisotropic HDDR powders with particle sizes of below $300 \mu\text{m}$ diam. The temperature coefficient of the intrinsic coercive force H_c of the bonded magnet is $-0.55\%/^\circ\text{C}$ in the temperature range from 25 to 100°C . The magnetization force needed for full magnetization of the bonded magnet is about twice the coercive force of the magnet, indicating that the magnetization mechanism is different from that of the rapidly solidified isotropic Nd-Fe-B magnet. In the early stage of the recombination step of the HDDR process (1 min desorption), three phases are produced, i.e., $\alpha\text{-(Fe,Co)}$, spherical NdH_2 and rimlike $\text{Nd}_2(\text{Fe,Co})_{14}\text{B}$ surrounding the NdH_2 particle. Further desorption makes the $\text{Nd}_2(\text{Fe,Co})_{14}\text{B}$ phase grow. © 1996 American Institute of Physics. [S0021-8979(96)38808-0]

I. INTRODUCTION

Resin-bonded Nd-Fe-B magnets made from rapidly solidified magnet powders have been increasingly used in many applications. The maximum energy products (BH_{max}) of these magnets are 12 MGOe at the most, since they are magnetically isotropic. The development of anisotropic bonded magnets possessing a larger maximum energy product than the isotropic magnets are, therefore, desired in the Nd-Fe-B magnet system.

The hydrogenation-decomposition-desorption-recombination (HDDR) process has been shown to induce a large coercivity in the Nd-Fe-B magnet system.¹⁻³ This process utilizes the phase transformation of the intermetallic $\text{Nd}_2\text{Fe}_{14}\text{B}$ compound with hydrogen. $\text{Nd}_2\text{Fe}_{14}\text{B}$ decomposes into NdH_2 , $\alpha\text{-Fe}$ and Fe_2B in hydrogen atmosphere at elevated temperatures, and then this decomposed mixture recombines to form the original $\text{Nd}_2\text{Fe}_{14}\text{B}$ compound in the subsequent hydrogen desorption step.³ By this process, original large crystalline grains of $\text{Nd}_2\text{Fe}_{14}\text{B}$ in the cast ingot are transformed into fine crystalline grains of about $0.3 \mu\text{m}$ diam, which is close to a size of a single magnetic domain of $\text{Nd}_2\text{Fe}_{14}\text{B}$.³ This fine microstructure is thought to be related to high coercivities of the HDDR magnet powders. The application of the HDDR process produces almost isotropic magnet powders in ternary Nd-Fe-B alloys. On the other hand, the substitution of Fe with Co and the addition of elements such as Ga, Zr, Nb, Hf, and Ta induces magnetic anisotropy in HDDR magnet powders.⁴⁻⁶ The appearance of magnetic anisotropy in the HDDR powders is due to the correlated c -axes orientation of the fine $\text{Nd}_2(\text{Fe,Co})_{14}\text{B}$ crystalline grains in each powder particle.⁶ The anisotropic HDDR magnet powder is now commercially available, and bonded magnets with maximum energy products larger than 15 MGOe are now available.⁷

In this report, the current status of anisotropic HDDR magnet powders and the bonded magnets made from them are presented. Also included are some results of the microstructural study on the Nd-Fe-Co-B-Zr alloy system in the desorption step of the HDDR process in order to understand the origin of the preferred alignment of the crystalline c -axes of the recombined $\text{Nd}_2(\text{Fe,Co})_{14}\text{B}$ crystalline grains.

II. EXPERIMENT

The alloy ingots of various compositions close to the $\text{Nd}_2(\text{Fe,Co})_{14}\text{B}$ stoichiometry, i.e., $\text{Nd}_{12-13}\text{Fe}_{\text{bal}}\text{B}_{5-8}\text{Co}_{10-20}\text{M}_{0.1-1}$ ($M = \text{Ga, Zr}$), were prepared by arc-melting constituent elements in an Ar gas atmosphere. The alloy ingots were subsequently homogenized at 1120°C for 20 h in an argon atmosphere, and then were crushed into blocks of sizes less than $20 \text{ mm} \times 20 \text{ mm} \times 20 \text{ mm}$. Those blocks were subjected to HDDR processing with the following condition: first heated up in atmospheric hydrogen gas from room temperature to 830°C , kept at this temperature for 10 min, evacuated for about 40 min reaching a high vacuum (10^{-5} Torr), and then quenched by Ar gas to room temperature. After this HDDR processing, the alloy blocks were crushed into powders of less than $420 \mu\text{m}$ diam for the bonded magnet production. Anisotropic bonded magnets were prepared in the following manner: The magnet powders were mixed with a resin binder, and the powders were placed in a mold and were aligned with a magnetic field of 24 kOe and pressed into a green compact, and finally the green compact was hardened at $100\text{--}170^\circ\text{C}$ for 1 h. The densities of bonded magnets so prepared are from 6.0 to 6.2 g/cm^3 . The magnetic properties of the powders and those of the bonded magnets were measured by a vibrating sample magnetometer (VSM) and a B-H tracer. The VSM data were corrected for the demagnetizing fields. The powder specimens for the mea-

FIG. 1. Particle size dependence of B_r and iH_c of the anisotropic HDDR magnet powder.

measurements were aligned with a magnetic field of 15 kOe and then consolidated into bricks with paraffin wax. Unless otherwise stated, the bonded magnets were magnetized in a pulsed magnetic field of 70 kOe before the measurement. In the long-term aging tests at elevated temperatures, the samples were periodically cooled to room temperature and their open-circuit remanent flux was measured with a digital fluxmeter. The microstructures of the sample powders were examined with a transmission electron microscope (TEM). The TEM specimens were prepared by molding the powders in resin, cutting it into a plate with a thickness less than 0.1 mm, and thinning it by the ion milling technique.

III. RESULTS AND DISCUSSION

A. Powder particle size dependence of magnetic properties

Figure 1 shows the powder particle size dependence of the residual induction, B_r , and intrinsic coercive force, iH_c , of the anisotropic HDDR powder of Nd-Fe-B-Co-Zr-Ga system. The largest value of B_r is obtained for magnet powders with diameters of 50–200 μm . These particle sizes are roughly the same as those of the original crystalline grain sizes of $\text{Nd}_2(\text{Fe},\text{Co})_{14}\text{B}$ phase in the starting alloy ingots. This suggests that the crystalline c -axis orientation of the original $\text{Nd}_2(\text{Fe},\text{Co})_{14}\text{B}$ grains of the alloy ingots may be maintained during the HDDR processing. The coercive force iH_c is almost constant and about 14 kOe for magnet powders with diameters of 50–420 μm . In magnet powders with diameters of less than 50 μm , the B_r and iH_c are smaller than those of larger particles by 1 kG and 1 kOe, respectively. This is considered to be due to the deterioration of these properties by the surface oxidation of the powder particle and also may be due to the stress introduced during the crushing operation in the powder production stage. This particle size dependence of magnetic properties is, however, relatively small, and magnet powder with a wide particle size distribution can be used for bonded magnet production. It is well known that a wide distribution of particle sizes helps to

FIG. 2. Demagnetization curves of the anisotropic bonded magnets made by using aligning magnetic fields of (A) 15 kOe and (B) 24 kOe, respectively.

produce a dense green compact, and this is favorable for the production of bonded magnets of high density and consequently with large BH_{max} .

Figure 2 shows the demagnetization curves of bonded magnets made from the anisotropic HDDR powder of Fig. 1 with particle diameters less than 300 μm . Raising the density of green compacts to 6.2 g/cm³ by applying a compacting pressure of 6 ton/cm², bonded magnets with BH_{max} of 18.5–20.5 MGOe were obtained. The value of BH_{max} depends mainly on the aligning field strength.

B. Temperature dependence of magnetic properties

Figure 3 shows temperature dependent demagnetization curves of the bonded magnet made from the anisotropic HDDR magnet powders in Fig. 1. The magnetic properties of the magnet at room temperature were: $B_r = 8.5$ kG, $iH_c = 12.5$ kOe, and $BH_{\text{max}} = 16.0$ MGOe. The temperature coefficients of B_r and iH_c in the temperature range of 25–100 °C were -0.10 and $-0.55\%/^{\circ}\text{C}$, respectively. The absolute value of the latter parameter is larger than that of an isotropic Nd-Fe-B bonded magnet made from the rapidly

FIG. 3. Temperature dependence of demagnetization curve of the anisotropic bonded magnet.

FIG. 4. Change in open-circuit remanent flux of the anisotropic bonded magnets during long-term aging tests.

solidified magnet powder ($-0.45\%/^{\circ}\text{C}$), but still lower than that of sintered Nd-Fe-B magnets ($-0.65\%/^{\circ}\text{C}$). These differences may be related to their different microstructures. The rapidly solidified powder is made of very small $\text{Nd}_2\text{Fe}_{14}\text{B}$ crystalline grains of about 50 nm diam and an amorphous boundary phase.⁸ The sintered magnet consists of $\text{Nd}_2\text{Fe}_{14}\text{B}$ crystalline grains of 10–50 μm diam and a non-magnetic Nd-rich boundary phase.⁹ In contrast to those microstructures, the HDDR magnet powder contains $\text{Nd}_2(\text{Fe},\text{Co})_{14}\text{B}$ crystalline grains of about 0.3 μm diam, which is comparable to that of the single magnetic domain of $\text{Nd}_2\text{Fe}_{14}\text{B}$, and essentially does not contain a boundary phase(s).⁶ This unique microstructure of the HDDR powder may affect its temperature coefficient of μH_c as well as its coercivity mechanism.

Figure 4 shows the change in the open-circuit remanent flux of the HDDR bonded magnets during long-term aging tests. The magnetic properties of the samples used in this test are the same as those shown in Fig. 3. Before the test, the magnets were coated with epoxy resin for protecting the samples against oxidation. After exposure to the air at 100 $^{\circ}\text{C}$ for 1000 h, the irreversible magnetic flux losses of the magnets with the permeance coefficients (B/H) of 2 and 5 are 8% and 5%, respectively. The flux losses of these samples were increased to 17% and 11% as the environmental temperature was raised to 125 $^{\circ}\text{C}$. Although the irreversible flux loss of the bonded magnets partly depends on the magnet production conditions such as the types of resin binders, the surface treatment of the powders and others, these aging test results suggest that the upper limit of operating temperatures for bonded magnets based on the anisotropic HDDR magnet powders is around 100 $^{\circ}\text{C}$.

C. Magnetization behavior of the HDDR magnet powder

Figure 5 shows the magnetization curve of an anisotropic HDDR powder compact thermally demagnetized and

FIG. 5. Magnetization curves of the specimens made from the anisotropic HDDR magnet powder.

that of an anisotropic bonded magnet demagnetized by a dc magnetic field antiparallel to the aligning field. The powder compact specimen was prepared by aligning the magnet powder without any resin binder, pressing the powder into a green compact and heating the compact to 550 $^{\circ}\text{C}$ for the thermal demagnetization. The specimen demagnetized by a dc field shows a smooth "S" shape magnetization curve with low permeabilities. On the other hand, the specimen thermally demagnetized exhibits a magnetization curve which slowly rises at low fields, and shows an inflection point around 10 kOe and then steeply rises at higher fields. These magnetization behaviors suggest that the magnetic domain structure of the anisotropic HDDR powder in the thermally demagnetized state is different from that of the one in the magnetically demagnetized state, and that the magnetic domain wall motion determines the magnetization behavior of this magnet powder. This magnetization behavior is quite different from that of rapidly solidified magnets or that of sintered magnets, and suggests that the coercivity mechanism would also be unique, i.e., neither the pinning type of rapidly solidified powder nor the nucleation type of sintered magnet.

Figure 6 shows the magnetizing field dependence of magnetic properties of the anisotropic bonded magnet with a high μH_c of 13 kOe (type H) which has been shown in the previous figures, and those of the magnet with a low μH_c of 10 kOe (type L). The type-L magnet is made from the anisotropic HDDR powder, the additives content of which is lower than that of the type-H magnet powder. The magnetic remanence (B_r) and the maximum energy product (BH_{max}) of both types of magnets are typically 9.0 kG and 17.5 MGOe, respectively, although the strength of their coercivities are different. The magnetic field strength required for full magnetization is about twice the intrinsic coercive force for both types of magnet, i.e., 30 kOe for the type-H magnet and 20 kOe for the type-L magnet. Although the reduction of the coercive force may be thought to restrict the range of operating temperature, the type-L magnet is a good candidate for many applications where the magnetization is difficult

FIG. 6. Magnetizing field dependence of magnetic properties of the anisotropic bonded magnets with H_c 's of 13 kOe (type H) and 10 kOe (type L), respectively.

because of the physical arrangement, typically radially oriented ring magnets with multiple poles.

D. Microstructural change in the desorption step

The microstructures of both the isotropic Nd-Fe-B and the anisotropic Nd-Fe-B-Co-M ($M = \text{Zr or Ga}$) HDDR powders are the same with regards to the size and morphology of their crystalline grains, and their boundary region structures. The only difference is the crystallographic orientations of the fine $\text{Nd}_2\text{Fe}_{14}\text{B}$ and $\text{Nd}_2(\text{Fe,Co})_{14}\text{B}$ crystalline grains. In order to understand the appearance of a preferred crystallographic orientation of the fine grains in the anisotropic magnet powder, the microstructural change of the Nd-Fe-Co-B-Zr alloy in the desorption step of the HDDR process was studied with TEM. Figure 7 shows TEM bright field images of the $\text{Nd}_{12.6}\text{Fe}_{\text{bal}}\text{Co}_{11.6}\text{B}_{6.0}\text{Zr}_{0.1}$ alloy taken during the desorption operation. The condition of the desorption was as follows: The alloy was first heated up in atmospheric hydrogen gas to 830 °C and hydrogenated at 830 °C for 10 min in 1 atm H_2 , and desorbed at this temperature for each period of time (1, 10, and 20 min), and subsequently quenched by Ar gas. The microstructure of the 1 min desorption consists of three phases: (1) spherical particles of about 20 nm diam (A, B, C, and J), (2) matrix phase (E, H, and I), and (3) rimlike phase of thickness of 30–50 nm (D, F, and G) which surround the spherical phase. The electron diffraction pattern indicates that the type (1) is NdH_2 of the fcc structure, and the type (2) is $\alpha\text{-(Fe,Co)}$ of the bcc structure. The type (3) can be attributed to $\text{Nd}_2(\text{Fe,Co})_{14}\text{B}$ or a related phase based on the energy dispersive x-ray analysis as well. After a 10 min desorption, the rimlike phase grows to 50–100 nm in thickness and can be clearly identified as

FIG. 7. TEM bright field images of the $\text{Nd}_{12.6}\text{Fe}_{\text{bal}}\text{Co}_{11.6}\text{B}_{6.0}\text{Zr}_{0.1}$ alloy hydrogenated at 830 °C for 10 min at 1 atm H_2 , desorbed for each period of time and subsequently quenched by Ar gas: (a) after 1 min, (b) after 10 min, and (c) after 20 min.

$\text{Nd}_2(\text{Fe,Co})_{14}\text{B}$ by the electron diffraction pattern. After a 20 min desorption, the recombination of the decomposed phases is completed, and the product is made of only fine grains of $\text{Nd}_2(\text{Fe,Co})_{14}\text{B}$ of about 300 nm diam. These observations show that in the desorption step the recombination reaction proceeds as the rimlike phase grows, and the rimlike $\text{Nd}_2(\text{Fe,Co})_{14}\text{B}$ phase may carry the direction of the c axis of the original large crystalline grain to the recombined fine crystalline grains. Uehara and co-workers reported that the fine undecomposed $\text{Nd}_2(\text{Fe,Co})_{14}\text{B}$ particles exist in the hydrogenated Nd-Fe-Co-B-Ga and Nd-Fe-Co-B-Ga-Zr alloys, and they proposed that these undecomposed particles should act as nuclei for the growth or recrystallization of the $\text{Nd}_2(\text{Fe,Co})_{14}\text{B}$ phase with a preferred crystallographic orientation during the desorption step.^{10,11} The TEM results of this study, however, cannot rule out the possibility of the formation of the rimlike $\text{Nd}_2(\text{Fe,Co})_{14}\text{B}$ phase by a rapid

recombination reaction after the complete decomposition, and it is still not clear whether the rimlike $\text{Nd}_2(\text{Fe},\text{Co})_{14}\text{B}$ phase originates from the original crystalline grain without any transformation or it is formed by the recombination of the decomposed products after the complete decomposition. In order to clarify this question, it is necessary to compare the ternary Nd-Fe-B system and the Nd-Fe-Co-B-Zr-(Ga) system(s) more thoroughly regarding their microstructural changes in the HDDR process and crystallographic relationships of the decomposed products.

IV. CONCLUSION

The magnetic properties of anisotropic Nd-Fe-B bonded magnets made from HDDR powders are reported. The results of recent microstructural studies on the appearance of the crystallographic orientation during the HDDR process are also described. The anisotropic bonded magnets are now commercially available and are used in several applications such as the automatic-iris mechanism of VTR cameras and other actuators. In order to extend the application areas of this magnet, research and development on further improvements of magnetic thermal stabilities and magnetization characteristics of the HDDR magnet powders are being conducted. Besides this, basic studies for clarifying the mechanism of the induction of high coercivities and the preferred crystallographic orientation in the HDDR powders are also in progress.

Sm₂Fe₁₇ interstitial magnets (invited)

K.-H. Müller, Lei Cao,^{a)} N. M. Dempsey,^{b)} and P. A. P. Wendhausen^{c)}
Institut für Festkörper- und Werkstofforschung Dresden e.V., 01171 Dresden, Germany

Various processing routes for making permanent magnets based on interstitially modified Sm₂Fe₁₇ have been recently developed. Zn bonding of coarse grained Sm₂Fe₁₇N₃ gives coercivities $\mu_0 H_c$ as high as 2.2 T. Effective methods to prepare highly coercive Sm₂Fe₁₇N₃ powders for polymer bonding are mechanical alloying and rapid quenching. With the very simple method of additional milling of coarse grained nitrided powders we achieved $\mu_0 H_c \approx 1.5$ T. A coercivity up to 3.5 T has been achieved by a modified HDDR procedure, reducing the particle size of the starting material by milling prior to the hydrogenation-disproportionation-desorption-recombination (HDDR) treatment. This is attributed to a better control of two critical parameters, namely grain size and the amount of unrecombined α -Fe accompanying the intermediate TbCu₇ structure-type phase. Resin bonded HDDR-Sm₂Fe₁₇N₃ magnets show an unexpected high initial susceptibility. This may be due to a strong magnetic interaction of the grains. To develop coercivity in Sm₂Fe₁₇C_{y>1} obtained by gas-solid reactions of Sm₂Fe₁₇ the same methods as those applied to Sm₂Fe₁₇N₃ can be successfully used. Fully dense magnets with a coercivity up to 1.5 T were made from the interstitially as well as substitutionally modified compound Sm₂Fe₁₅Ga₂C₂ by hot pressing of highly coercive powders. © 1996 American Institute of Physics. I. INTRODUCTION

The discovery of the excellent properties of Nd₂Fe₁₄B in 1983 and its subsequent commercial success inspired a search for still improved ternary rare-earth iron compounds. A promising way to do that was to modify R₂Fe₁₇ which is the most iron-rich binary rare-earth iron intermetallic compound but it is unsuitable for permanent magnets because its Curie temperature is too low and its magnetocrystalline anisotropy is easy plane. A remarkably higher $T_c = 253$ °C was found for Sm₂Fe₁₇H₂,¹ but this interstitially modified compound still has an unsuitable magnetic anisotropy and the hydrogen desorbs at about 300 °C.² A similar increase of T_c and a uniaxial magnetic anisotropy were achieved by introducing carbon into the melt,³ which yields Sm₂Fe₁₇C_x ($x \leq 1.5$). However, these compounds have not been able to match the intrinsic properties of Nd₂Fe₁₄B. An essential step was taken, when the interstitial compounds Sm₂Fe₁₇N_x and Sm₂Fe₁₇C_x ($x = 2-3$) were prepared by low-temperature solid-gas reactions.^{4,5} The carbon and nitrogen atoms occupy octahedral interstitial sites in the rhombohedral 2:17 structure. There are two main effects of the interstitial atoms: (i) an increase of T_c and of the spontaneous polarization J_s , caused by a lattice expansion resulting in a change in the electronic structure of the Sm₂Fe₁₇ sublattice,⁶ and (ii) the formation of a strong uniaxial magnetic anisotropy, because the positions of the C and N atoms are very close to the rare-earth atoms and therefore create a strong crystalline electric field at the site of the 4f electrons.⁷⁻⁹ The Sm₂Fe₁₇ interstitial compounds have intrinsic properties comparable to or even better than those of Nd₂Fe₁₄B (see Table I). The

problem was then to develop coercivity and to find processes for making good permanent magnets. High-temperature powder metallurgy could not be used because the interstitial compounds mentioned above disproportionate when heated above about 600 °C.¹⁰ One strategy to overcome this difficulty was to imitate sintering with a low-melting metal where most encouraging results were obtained with zinc.¹¹⁻¹⁴ Successful methods for making fine grained coercive Sm₂Fe₁₇N_x or Sm₂Fe₁₇C_x powders for polymer bonded magnets are mechanical alloying,¹⁵ melt spinning,¹⁶ intense milling after the interstitial modification,¹⁷ and hydrogenation-disproportionation-desorption-recombination (HDDR).^{2,18} Weak points of the interstitially modified Sm₂Fe₁₇ magnets, so far, are their low values of remanence B_r and energy density $(BH)_{max}$, which is due to (i) the presence of nonmagnetic phases,¹⁰ (ii) low densities, and (iii) missing grain alignment in nanostructured powders. A very interesting result is that the substitutionally modified compounds Sm₂Fe_{17-y}Ga_yC₂ ($y \leq 3$) can be prepared by melting and are stable at quite high temperatures (see Table I).¹⁹ This enables the application of heat treatments for magnetic hardening²⁰ as well as hot pressing to get fully dense magnets, as will be shown in this paper. The values of B_r and $(BH)_{max}$ may also

be increased by the effect of so-called remanence enhancement caused by magnetic interaction of the interstitial 2:17 phase with a soft magnetic phase (e.g., α -Fe) in nanostructured two-phase materials.²¹ The coercivity of Zn bonded coarse grained $\text{Sm}_2\text{Fe}_{17}\text{N}_3$ magnets is mainly controlled by nucleation of reverse domains.^{22,23} On the other hand, the magnetization processes in fine grained interstitial magnets is not yet well understood.²⁴

II. INTERSTITIAL AND SUBSTITUTIONAL MODIFICATION OF $\text{Sm}_2\text{Fe}_{17}$

Table I compares the intrinsic magnetic properties, Curie temperature T_c , room-temperature values of spontaneous polarization J_s , and anisotropy field H_A , of some modified $\text{Sm}_2\text{Fe}_{17}$ compounds with those of $\text{Nd}_2\text{Fe}_{14}\text{B}$. Obviously, only $\text{Sm}_2\text{Fe}_{17}\text{N}_3$ and $\text{Sm}_2\text{Fe}_{17}\text{C}_3$ match the properties of $\text{Nd}_2\text{Fe}_{14}\text{B}$ and they have even higher Curie temperatures. The temperature T_s also given in Table I represents a stability limit for the considered phases, which is due to melting, disproportionation, or desorption. A disadvantage of $\text{Sm}_2\text{Fe}_{17}\text{N}_3$ and $\text{Sm}_2\text{Fe}_{17}\text{C}_3$ is their low value of T_s , which excludes high-temperature methods for magnetic hardening or consolidation. As an encouraging result the thermal stability of $\text{Sm}_2\text{Fe}_{17}\text{C}_x$ ($x > 1.5$) could be considerably improved by a partial substitution of Fe by Ga (see Table I).

In the 2:17 structure three $9e$ octahedral interstitial sites per formula unit can be occupied by C or N atoms. In most practical cases, however, the net concentration x in $\text{Sm}_2\text{Fe}_{17}\text{N}_x$ or $\text{Sm}_2\text{Fe}_{17}\text{C}_x$ is less than 3 and there is a controversial discussion whether partially nitrogenated or carbonated $\text{Sm}_2\text{Fe}_{17}$ is single phase or not.¹⁰ We have also investigated this problem. $\text{Sm}_2\text{Fe}_{17}\text{N}_x$ ($x < 3$) material was prepared by a gas-interstitial modification of coarse $\text{Sm}_2\text{Fe}_{17}$ powder which was exposed to N_2 gas under 10^5 Pa at 450°C for different times in order to get different degrees of nitrogenation. The magnetic domain structure of the powder particles was observed by the Bitter technique. The local x concentration was measured along various lines by electron probe microanalysis (EPMA). Figure 1 shows typical results for a nonfully nitrided $\text{Sm}_2\text{Fe}_{17}$ particle. Due to incomplete nitrogenation we find three regions of the particle: (i) a non-nitrided core, (ii) a fully nitrided outer shell, and (iii) a smooth transition region a few microns thick. It should be noted that the heterogeneous material shown in Fig. 1 is far from thermal equilibrium. To get more insight into the phase structure of partially nitrided samples in thermal equilibrium we homogenized them at 450°C in a small sealed quartz tube and analyzed them by differential scanning calorimetry (DSC). As shown in Fig. 2, all samples with $0.3 \leq x \leq 3$ are characterized by only one exothermal peak indicating the presence of only one phase which decomposes at a certain temperature depending on x . Similar results were found for partially carbonized samples.

III. MAGNETIC HARDENING

A. Rapid quenching

Nanocrystalline Sm-Fe alloys have successfully been produced by rapid quenching.¹⁶ Besides the well-known

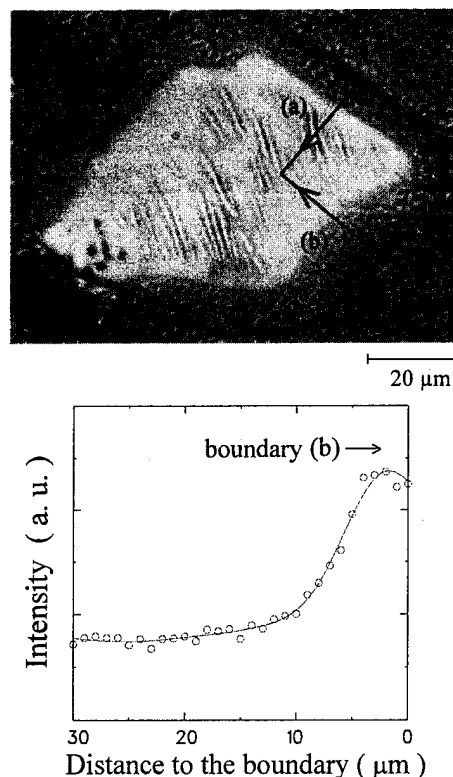

FIG. 1. Domain pattern (Bitter technique) of a non-fully-nitrided $\text{Sm}_2\text{Fe}_{17}$ particle and nitrogen concentration in the diffusion layer measured by EPMA in a scan along line (b).

equilibrium phases of the binary Sm-Fe system, a hexagonal TbCu_7 -type phase shows up in melt spun ribbons. Nitrogenation leads to an overall improvement of the hard magnetic properties. To get optimum properties it is necessary to avoid the TbCu_7 structure.¹⁶

B. Mechanical alloying

Mechanical alloying was the first successful method for making highly coercive $\text{Sm}_2\text{Fe}_{17}\text{N}_x$ magnets.¹⁵ Powders of Sm and Fe are cold worked in a ball mill to yield an intimate mixture of nanocrystalline iron and an amorphous Sm-Fe alloy. This is then heat treated at 730°C to induce crystallization of $\text{Sm}_2\text{Fe}_{17}$. The powder is then nitrogenated or car-

FIG. 3. Coercivity vs annealing temperature for a mechanically alloyed $\text{Sm}_2\text{Fe}_{17}\text{Ga}_2\text{C}_2$ magnet (annealing time: 1 h).

bonated by a solid-gas reaction in N_2 or C_2H_2 atmospheres at 450–500 °C to yield material with extremely high coercivity, up to $\mu_0 H_c = 3$ T. We used mechanical alloying to prepare coercive nanocrystalline $\text{Sm}_2\text{Fe}_{15}\text{Ga}_2\text{C}_2$ powder. Elemental Sm, Fe, and Ga were milled together with a Fe–C prealloy in a planetary ball mill (Retsch 400 M) for 60 h. The formation of material with the $\text{Th}_2\text{Zn}_{17}$ -type structure was confirmed by x-ray diffractometry and DSC. As shown in Fig. 3 an optimum value of coercivity of about 1.5 T was achieved by a heat treatment at 850 °C (for 1 h). Similar results are reported in Ref. 20.

C. Milling subsequent to nitrogenation or carbonation

Ball milling is a widely used technique for magnetic hardening of rare-earth transition-metal compounds. Here, we will present results on milling of the material after the interstitial modification.

The coercivity $\mu_0 H_c$ of $\text{Sm}_2\text{Fe}_{17}\text{N}_3$ prepared by gas-solid reactions, can be remarkably increased by milling from about 0.3 to 1.5 T.¹⁷ As shown in Fig. 4 domain structures are clearly visible in particles of a not additionally milled powder, but in the additionally milled state they can hardly be seen. This indicates that the seemingly large particles in Fig. 4(b) are in reality agglomerates of small particles or cold-welded single-domain crystallites isotropically distributed. Obviously in such a microstructure no classical domain structure can be formed. Enhancement in coercivity by fragmentation of big particles into smaller ones is a well-known effect of milling. We have also prepared nanostructured $\text{Sm}_2\text{Fe}_{15}\text{Ga}_2\text{C}_2$ powders by intense milling of homogenized ingots, with the $\text{Th}_2\text{Zn}_{17}$ -type structure, and a subsequent annealing. As shown in Fig. 5 an optimum coercivity $\mu_0 H_c$ of 1.2 T was achieved by a heat treatment for 15 min at 700 °C.

D. Hydrogenation-disproportionation-desorption-recombination (HDDR)

The HDDR process is a well-established method to produce highly coercive fine grained powders for bonded Nd–Fe–B permanent magnets. In this section we will present some results on the adaptation of HDDR for magnetic hardening of interstitially modified $\text{Sm}_2\text{Fe}_{17}$ compounds.² At room temperature the amount of hydrogen absorbed can

FIG. 4. Optical micrographs (Bitter technique) for two resin bonded $\text{Sm}_2\text{Fe}_{17}\text{N}_3$ powders: (a) not additionally milled, (b) additionally milled for 600 min.

reach about 5 atoms per unit formula. This results in strong volume expansion of about 3 vol % causing the material to become friable or even to decrepitate. With increasing temperature, hydrogen is desorbed and at 500 °C its content is almost zero. For a hydrogen pressure of 10^5 Pa the disproportionation of $\text{Sm}_2\text{Fe}_{17}$ into SmH_x and Fe occurs above 520 °C. Hydrogen desorbs completely from SmH_x when the material is heated above 570 °C under vacuum and the intimate mixture of Sm and Fe reverts to fine grained $\text{Sm}_2\text{Fe}_{17}$. This recombination process was studied using x-ray diffractometry (see Fig. 6). At low temperatures the material tends to crystallize in the TbCu_7 -type structure characterized by the absence of superstructure reflections. At higher temperatures the superstructure reflections start appearing, indicating the

FIG. 5. Coercivity vs annealing temperature for a $\text{Sm}_2\text{Fe}_{15}\text{Ga}_2\text{C}_2$ powder annealed after ball milling.

FIG. 6. X-ray patterns of $\text{Sm}_2\text{Fe}_{17}$ in the disproportionated state [(●) nearly amorphous SmH_x] and recombined for 1 h at different temperatures, showing the transition from the TbCu_7 structure to the $\text{Th}_2\text{Zn}_{17}$ structure which is characterized by the superstructure reflections (◆).

presence of the $\text{Th}_2\text{Zn}_{17}$ -type structure, but only for temperatures as high as 1000 °C where the sharp superstructure reflections show up. As expected, the recombined material shows grain sizes much smaller than those of the parent alloy. This is shown in Fig. 7 where it can also be seen that the

FIG. 7. SEM micrographs showing the microstructure of HDDR $\text{Sm}_2\text{Fe}_{17}$ recombined at 700 °C for different times (left-hand side column) and for 1 h at different temperatures (right-hand side column).

FIG. 8. Coercivity of HDDR $\text{Sm}_2\text{Fe}_{17}\text{N}_3$ as a function of duration of milling prior to the hydrogenation.

final grain size strongly depends on temperature and duration of the recombination step. After proper nitrogenation the coercivity of the HDDR material will strongly depend on the recombination conditions. For our conditions, optimum values of coercivity $\mu_0 H_c$ up to 1.7 T were achieved for material recombined at a temperature of about 750 °C for 1 h. Such a material shows grain sizes of about 500 nm. As shown in Fig. 8 the coercivity $\mu_0 H_c$ of nitrogenated HDDR $\text{Sm}_2\text{Fe}_{17}$ has been increased from 1.5 to 3.5 T by milling prior to the HDDR treatment with an addition of excess Sm. Figure 9 shows an optical micrograph of HDDR $\text{Sm}_2\text{Fe}_{17}$ which was recombined at a too high temperature (1000 °C). The material has an inhomogeneous microstructure consisting of large grains coexisting with much finer grains. The larger grains are concentrated in the core of the particles while the finer grains form an outer shell. A possible reason for this is that material in this outer shell remains in the disproportionated state as long as the flow of hydrogen, being desorbed from within the core, can prevent recombination. As a consequence of this, the earliest formed grains within the core have longer time to grow. By milling the material before the HDDR treatment, shorter times are needed for complete hydrogen desorption and subsequent recombination and therefore grain growth can be better controlled. The enhancement in coercivity achieved by adding

FIG. 9. Optical micrograph of a big HDDR $\text{Sm}_2\text{Fe}_{17}$ particle recombined for 30 min at 1000 °C, showing a core of large grains surrounded by a shell of fine grains.

FIG. 10. Demagnetization curves of mechanically alloyed $\text{Sm}_2\text{Fe}_{15}\text{Ga}_2\text{C}_2$ (—): annealed for 1 h at 850 °C and cold pressed, (---): annealed for 30 min at 850 °C and hot pressed.

excess Sm is mainly attributed to the suppression of $\alpha\text{-Fe}$. Furthermore, the formation of additional minority phases cannot be excluded.

E. Zinc bonding

The original idea of Zn bonding of $\text{Sm}_2\text{Fe}_{17}\text{N}_3$ or $\text{Sm}_2\text{Fe}_{17}\text{C}_3$ was to use a low melting metal which might wet and separate the hard magnetic grains, thus imitating liquid-phase sintering.^{11–14} Coercivities $\mu_0 J H_c$ as high as 2.2 T have been achieved up to now. However, we found that liquid Zn does not play an important role. The main effect of Zn is to form paramagnetic intermetallic phases around the 2:17 particles, which decouple them magnetically, smooth them, and remove $\alpha\text{-Fe}$. Though Zn-bonded coarse $\text{Sm}_2\text{Fe}_{17}(\text{N,C})_x$ powders were successfully textured, their energy density $(BH)_{\text{max}}$ did not exceed 80 kJ/m³, which is caused by a relative low density and the presence of nonmagnetic phases. Zinc bonding was also successfully combined with other methods of magnetic hardening. For HDDR $\text{Sm}_2\text{Fe}_{17}$ which was nitrogenated and then Zn bonded we achieved $\mu_0 J H_c = 3$ T. A value of 4.4 T is reported for mechanically alloyed $\text{Sm}_2\text{Fe}_{17}$ which was Zn bonded after nitrogenation.²⁵

IV. REMANENCE AND ENERGY DENSITY

In principle, the remanence B_r can be increased by (i) grain alignment, (ii) consolidation, (iii) avoiding nonferromagnetic phases, and (iv) exploiting the effect of remanence enhancement due to magnetic interaction. The best combination of grain alignment, high density, and small content of nonmagnetic phases has been reported in Ref. 26. A remanence of 0.9–1.0 T and an energy density of about 160 kJ/m³, both related to the real density, were achieved for compression-molded (epoxy bonded) $\text{Sm}_2\text{Fe}_{17}\text{N}_3$. Remanence enhancement has been achieved by producing a coherent nanocrystalline structure in mechanically alloyed, isotropic $\text{Sm}_7\text{Fe}_{93}$ -nitride powders consisting of $\alpha\text{-Fe}$ and $\text{Sm}_2\text{Fe}_{17}\text{N}_3$.²¹

We have increased the density of the mechanically alloyed $\text{Sm}_2\text{Fe}_{15}\text{Ga}_2\text{C}_2$ described in Sec. III B (see Fig. 3) by hot pressing. This is possible because the material is stable

up to high temperatures (see Table I). Hot pressing resulted in a density of 7.6 g/cm³, i.e., 97% of the full density. As shown in Fig. 10 the remanence of the hot-pressed material is nearly half of the spontaneous polarization of $\text{Sm}_2\text{Fe}_{15}\text{Ga}_2\text{C}_2$.

V. MAGNETIZATION PROCESSES

For compounds such as $\text{Sm}_2\text{Fe}_{17}\text{N}_x$ or $\text{Sm}_2\text{Fe}_{17}\text{C}_x$ ($1 < x$) the domain-wall width δ ranges from 2 to 5 nm and the critical single-domain particle size D_c from 200 to 500 nm. The grain size D of typical fine grained magnets, made from these compounds by rapid quenching, mechanical alloying, intense milling, or HDDR, lies between these two characteristic lengths, $\delta \ll D \leq D_c$. Therefore, a classical domain structure with 180° domain walls cannot be formed and the concepts of nucleation-type magnets or pinning-type magnets, successfully used to analyze coercivity of coarse grained materials such as Zn-bonded $\text{Sm}_2\text{Fe}_{17}\text{N}_3$ or $\text{Sm}_2\text{Co}_{17}$ -type magnets, will fail. The details of the coercivity mechanisms as well as the domain structures in fine grained materials are not well understood and represent an important area for further research. In a reasonable approximation, these materials can be considered as systems of interacting single-domain particles where the type and strength of the interaction is controlled by the structure, the thickness, and the composition of the grain boundaries. The magnetization direction of a given grain will not only depend on the applied field and on the magnetic prehistory of that grain but also on the magnetization state of its neighboring grains. For melt-spun Nd-Fe-B it was shown that the interaction may result in magnetic structures called interaction domains.²⁷ Two well-known methods to study the interaction by means of magnetic measurements are (i) Wohlfarth's remanence analysis, and (ii) an analysis of initial magnetization curves measured on samples with different magnetic prehistories.²⁴ In the following we will present some results obtained by method (ii) for two different types of fine grained $\text{Sm}_2\text{Fe}_{17}\text{N}_3$. The samples were prepared by milling after nitrogenation for 600 min and by HDDR. As shown in Fig. 11, the demagnetization curves of both materials are similar with coercivities $\mu_0 J H_c$ of about 1.5 T, but their initial magnetization curves are very different. The susceptibility $\chi \sim dJ/dH(H \rightarrow 0)$ of the milled material does not depend on the magnetic prehistory, as predicted for systems of noninteracting single-domain particles. The HDDR sample shows a behavior similar to that of nucleation controlled magnets:²² the susceptibility is much larger in the thermally demagnetized state than in the field demagnetized state. This result is not yet well understood. Possibly there is a strong exchange interaction between the grains, resulting in interaction domains similar to those reported in Ref. 27. The investigation of the domain structure in the HDDR material are in progress.

VI. CONCLUSIONS

Various processing routes are now established for developing coercivity above 1.5 T for interstitial 2:17 materials: mechanical alloying, rapid quenching, different milling procedures, HDDR, metal bonding, and combinations of these

FIG. 11. Demagnetization curves (—) and initial magnetization curves measured after thermal demagnetization (th) and dc field demagnetization (dc) for resin bonded $\text{Sm}_2\text{Fe}_{17}\text{N}_x$ powders prepared by HDDR (recombination for 1 h at 775 °C) or by additional milling after nitrogenation for 600 min.

methods. The highest values of $\mu_0 J H_c$, reported so far, are 3.5 T for HDDR $\text{Sm}_2\text{Fe}_{17}\text{N}_3$ and 4.4 T for Zn bonded mechanically alloyed $\text{Sm}_2\text{Fe}_{17}\text{N}_3$. The prospects of interstitially modified $\text{Sm}_2\text{Fe}_{17}$ will depend on the development of effective processing routes for magnets with appropriate values of B_r and $(BH)_{\max}$ which are now limited by the presence of nonmagnetic phases, pores, and missing grain alignment (in the case of fine grained materials). The highest value of $(BH)_{\max}$, reported so far, is 160 kJ/cm³ for compression-molded epoxy-bonded $\text{Sm}_2\text{Fe}_{17}\text{N}_3$ (with $\rho \approx 5.9$ g/cm³, $B_r \approx 0.98$ T $\mu_0 J H_c = 0.8$ T). There are prospects for enhancing $(BH)_{\max}$ by (i) stabilizing the interstitial compounds by a partial substitution of Fe by elements such as Ga, and (ii) exploiting the phenomenon of remanence enhancement in fine grained two phase materials. Interstitially modified $\text{Sm}_2\text{Fe}_{17}$ materials, in particular those prepared by HDDR, show interesting aspects of magnetization processes connected with nonconventional domain structures.

Disorder and noncollinear magnetism in permanent-magnet materials (invited)

R. Lorenz and J. Hafner^{a)}

Institut für Theoretische Physik, Technische Universität Wien, Wiedner Hauptstrasse 8-10, A-1040 Wien, Austria

We report calculations of the noncollinear magnetic structures and of the magnetic anisotropies of $\text{YFe}_{12-x}\text{Mo}_x$ permanent magnets with the ThMn_{12} structure, using a novel variant of a spin-polarized tight-binding-linear-muffin-tin-orbital technique allowing for local spin-quantization axes on each site and considering spin-orbit coupling. The ternary $\text{YFe}_{12-x}\text{Mo}_x$ compounds crystallize in the tetragonal ThMn_{12} structure which can be stabilized only by the partial substitution of Fe by an early transition metal like Mo. We show that the substitutional disorder leads to canted spin-structures at low Mo content ($x \sim 1$) and to spin-glass-like behavior at higher Mo content ($x \sim 3$). We also find that the character of the anisotropy changes from uniaxial to planar with higher Mo content. © 1996 American Institute of Physics. [S0021-8979(96)39008-1]

Permanent magnet materials are of highest technological importance. The properties that characterize a good permanent magnet are high Curie temperature, a large saturation magnetization, and a large uniaxial anisotropy. In recent years, it has been shown that rare-earth-transition-metal compounds of the type $\text{REFM}_{12-x}\text{M}_x$ (RE=Y, Gd, Nd, Sm; TM=Fe, Co; M=Ti, V, Cr, Mo) with the body-centered tetragonal ThMn_{12} structure have a high-potential as permanent magnets.¹⁻¹¹ Their properties can even be improved by nitrogenation. The problematic point is that at least a partial substitution of Fe or Co by a transition element with an only partially filled d band or by silicon is necessary to stabilize the ThMn_{12} structure of the otherwise metastable REFe_{12} or RECo_{12} compound. This substitution leads to a reduction of magnetization (although the compounds remain magnetically ordered up to $x=4$), and in the RE-Fe compounds possibly also to the formation of noncollinear spin structure.

X-ray¹ and neutron² diffraction as well as Mössbauer experiments⁷ show that the M atoms occupy preferentially the (8i) sites of the tetragonal ThMn_{12} structure. Both magnetization measurements^{8,9} and Mössbauer studies^{7,8} show a decreasing moment with increasing x . However, it turns out that the average hyperfine fields derived from the Mössbauer spectra cannot be converted to magnetic moments with a constant (i.e., independent of x) scaling factor. This suggests that with increasing M -metal content (and hence increasing disorder) a noncollinear (canted) spin-structure develops. The assumption of a noncollinearity of the magnetic moments is supported by low-field magnetization and coercivity measurements in YFe_9Mo_3 indicating spin-glass behavior.⁸ Investigations of the magnetic anisotropy^{10,11} have been interpreted in terms of a change from uniaxial to planar anisotropy. Spin-polarized electronic structure calculations for hypothetical ordered $\text{YFe}_{12-x}\text{Mo}_x$ ($x=0,4$) compounds^{3,6} and for supercells simulating disordered $\text{YFe}_{12-x}\text{Mo}_x$ ($x=1,2,3,4$) alloys⁸ predict the existence of magnetic order

up to $x=4$, but the calculated moment decreases much more slowly than observed. This again is compatible with noncollinearity of the magnetic moments.

The possible reason for the appearance of noncollinear spin structures in disordered $\text{YFe}_{12-x}\text{Mo}_x$ lies in frustrated competing ferro- and antiferromagnetic exchange interactions. It is well known that the distance-dependence of the Fe-Fe exchange interactions follows a Slater-Néel curve with a zero close to $d_{\text{Fe-Fe}} \sim 2.45$ Å. In the $\text{YFe}_{12-x}\text{Mo}_x$ compounds, the Fe-Fe nearest-neighbor distances vary between 2.38 Å and 2.65 Å. Hence, the exchange coupling is antiferromagnetic in the Fe-Fe pairs with the shortest bond lengths and ferromagnetic at larger distances. It has been pointed out¹² that the existence of strong antiferromagnetic interactions is very important for the high Curie-temperatures and large anisotropies of the $\text{YFe}_{12-x}\text{M}_x$ and Y_2Fe_{17} compounds. Collinear ferromagnetic ordering is possible only if the antiferromagnetic coupling is outweighed locally by stronger ferromagnetic interactions. This is possible only in the perfect crystal. Substitutional disorder breaks the balance and leads to the formation of canted magnetic moments. In principle, the situation is similar to the case of asperomagnetic phases in Fe-rich amorphous alloys.

In recent years, several attempts have been made to adapt existing codes for band-structure calculations in the local-spin-density approximation to noncollinear spin structures.^{13,14} However, these generalizations of the augmented-spherical-wave (ASW) and linear-muffin-tin-orbital (LMTO) codes are applicable only to systems with a small number of degrees of freedom in the spin structure.

Recently, two of us have proposed a novel approach based on the mapping of the LSDA Hamiltonian onto a real-space tight-binding Hubbard Hamiltonian:¹⁵

$$\mathbf{H} = \mathbf{H}_{\text{band}} + \mathbf{H}_{\text{exch}} + \mathbf{H}_{\text{so}} \quad (1)$$

where \mathbf{H}_{band} describes the nonmagnetic part of the band structure, \mathbf{H}_{exch} the magnetic exchange splitting, and \mathbf{H}_{so} the spin-orbit coupling. The two-center tight-binding Hamiltonian \mathbf{H}_{band} is constructed via a canonical transformation from the selfconsistent scalar-relativistic LMTO Hamiltonian in the atomic sphere approximation.¹⁶ The formulation of the

exchange part is based on the assumption that the local exchange splitting Δ_{il} is proportional to the local spin polarization,

$$\Delta_{il} = I\mu_{il}, \quad (2)$$

with an effective Stoner parameter I , leading to

$$\mathbf{H}_{\text{exch}} = -\frac{1}{2} \sum_{ilm} \Delta_{il} \sum_{ss'} X_{\zeta_i, ss'} c_{ilms}^\dagger c_{ilms'}, \quad (3)$$

where

$$\mathbf{X}_{\zeta_i} = \mathbf{D}_{\zeta_i} \sigma_z \mathbf{D}_{\zeta_i}^\dagger \quad (4)$$

is the local Pauli spin-matrix σ_z referring to the local quantization axis ζ_i , rotated to a global spin axis (the \mathbf{D}_{ζ_i} are the rotation matrices). The ansatz equation (3) for the exchange part of the Hamiltonian is based on the observation that the proportionality equation (2) holds exactly, with a universal value $I = (0.95 \pm 0.015)$ eV for all 3d- and 4d-metals, if the local exchange splitting Δ_{il} is defined in terms of the difference in the position of the center of gravity of the spin-up and spin-down bands¹⁷ (for a general discussion of the mapping of the LSDA exchange-correlation potential on Hubbard-(or Stoner-)type models, see, e.g., Anisimov *et al.*,¹⁸ here we only note that in our case the effective Stoner I has to be identified with Hund's rule exchange). A local effective Stoner-parameter I_{il} can be derived from the ab initio LMTO calculations in the collinear limit. For the $\text{YFe}_{12-x}\text{Mo}_x$ compounds, we find that the calculated I_{il} 's agree very well with the universal value. The spin-orbit-coupling term is given by

$$\mathbf{H}_{\text{so}} = \sum_i \xi_i \sigma_i \cdot \mathbf{L}_i, \quad (5)$$

where ξ_i is the spin-orbit-coupling matrix element calculated with the self-consistent scalar relativistic wavefunctions.

The self-consistent spin-structure is then calculated using an iterative real-space recursion algorithm. Starting with a random distribution of the local spin-quantization axes ζ_i , for each atomic site i the local spin-polarized partial densities of state $n_{ilms}(E)$ for spins parallel and perpendicular to ζ_i are calculated using the recursion method.¹⁹ Integrating the $n_{ilms}(E)$ up to the Fermi level defines the updated local magnetic moment μ_{ilm} . In general, μ_{ilm} will have transverse components with respect to ζ_i and the new local quantization axis ζ'_i must be rotated into the direction of the moment. The calculation is iterated until the directions are stabilized and selfconsistency according to Eq. (2) has been achieved. The main advantage of this technique is that in essence we calculate the magnetic force that rotates the moment into the direction of easy magnetization. Our technique is similar in spirit to the method proposed by Krey *et al.*^{20,21} However, Krey *et al.* used an empirical TB-Hamiltonian for the band-part, and treated the Stoner parameter (they call it a Hubbard U , somewhat misleadingly) as an adjustable parameter. In contrast, our approach is parameter-free. Our technique has been used to treat spero- and asperomagnetism in amorphous Fe and Fe-Zr, Fe-Y alloys,²² as well as spin-glass behavior in CuMn solid solutions.²³ The technique is also very useful in the absence of competing exchange interactions because it immediately predicts the easy axis of magnetization and allows, by repeating the calculation in the presence of a magnetic field perpendicular to the easy axis, to determine the value of the anisotropy constant without calculating very small energy differences.²² Here, we concentrate on the non-collinearity induced by the substitutional disorder, but it is

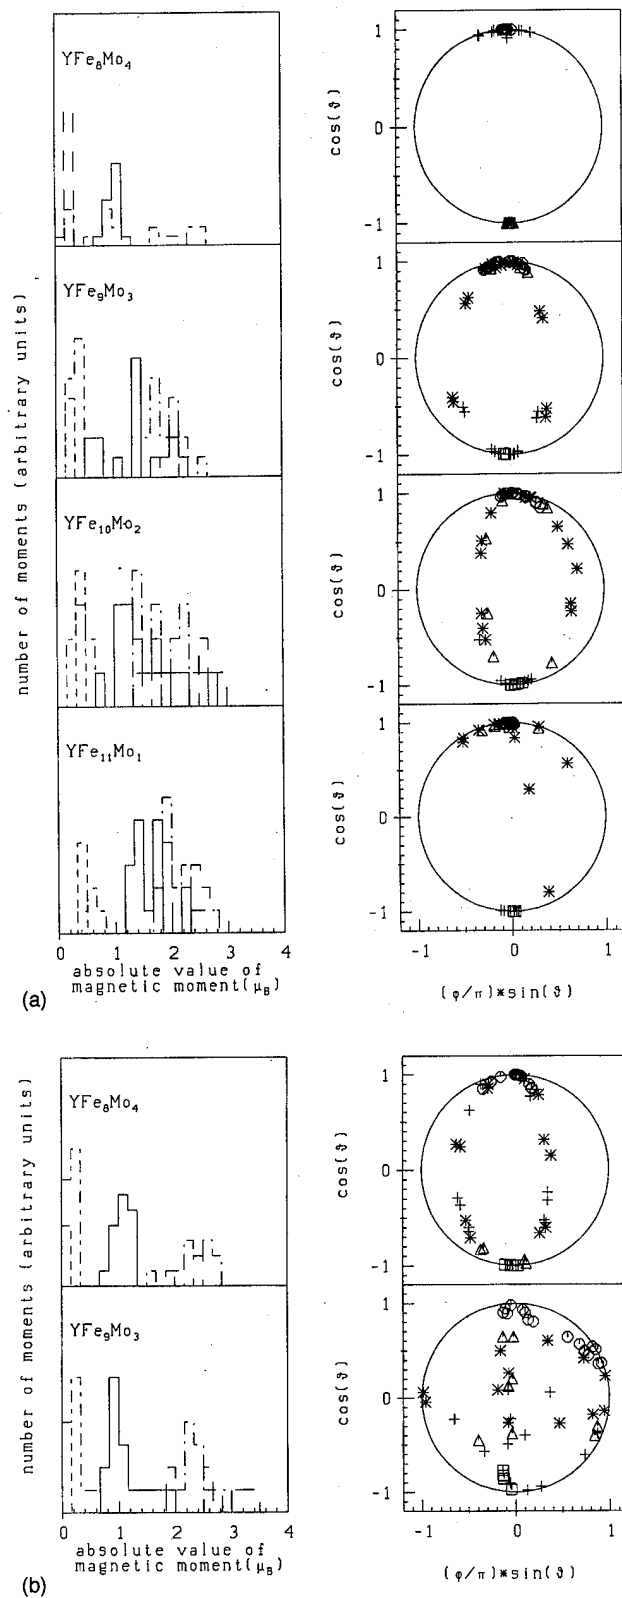

FIG. 1. Distribution of the local magnetic moments in disordered $\text{YFe}_{12-x}\text{Mo}_x$ alloys. Left column: distribution of the absolute values $|\mu_i|$ in the form of a histogram [full line—Fe(8*i*), dashed line—Fe(8*j*), dash-dot—Fe(8*f*), dotted—Y, dash-dot-dot—Mo]. Right column—polar diagram for the orientation of the moments [star—Fe(8*i*), triangle—Fe(8*j*), circle—Fe(8*f*), cross—Mo, square—Y]. Part (a) represents the case where the Mo-atoms occupy only 8*i* sites, part (b) the case where one Mo-atom per formula unit was placed on an 8*j* site.

FIG. 2. Vector models representing the spin-structures in disordered $\text{YFe}_{12-x}\text{Mo}_x$ alloys. Part (a) refers to Mo-substitution on the Fe(8*i*)-sites only, part (b) to Mo-substitution on the (8*i*) and (8*j*) sites (cf. text).

important to include the local anisotropies arising from the spin-orbit coupling in the calculations.

The calculations have been performed for a periodically repeated supercell containing 52 atomic sites (four formula

units or two ThMn_{12} unit cells). In a first series, Mo was substituted only on randomly selected $8i$ -sites (note that in this case YFe_8Mo_4 is again a fully ordered intermetallic compound). In a second series, for $x=3$ and $x=4$, one Mo-atom per formula unit was placed on an $8j$ -site instead of an $8i$ -site. The local spin-polarized DOS, local moments and spin splittings are calculated selfconsistently on all 52 sites, using 25 recursion steps for d -states and 9 recursion steps for s - and p -states. The results for the absolute values of the local moments (averaged over the crystallographically equivalent sites) and for the average moment per formula unit are given in Table I. If the Mo-atoms occupy only the $8i$ sites, we find a reduction of the calculated macroscopic magnetization compared to the collinear case, whereas the absolute values of the local moments are only little affected. This reduction is 12% for $x=1$, 40% for $x=2$, and 30% for $x=3$, whereas for $x=4$ a collinear configuration is retained as expected. This means that for larger Mo content these calculations do not reproduce the observed reduction of the magnetic moment. If for $x=3,4$ some Mo atoms are put on the $8j$ sites, the macroscopic magnetization drops dramatically and is now in good agreement with experiment. Occupation of the $8j$ sites occurs only for high global Mo concentrations. It is important to emphasize that although due to the disorder the global magnetization is strongly reduced, the local magnetic moments are even increased on the $8i$ - and $8j$ -Fe sites and only slightly reduced on the $8f$ -Fe sites. The negative moments carried by the Y and Mo atoms is only induced by the strong covalent coupling of the Y and Mo d bands to the minority-spin band of Fe. Hence, the Y and Mo local moments are also only weakly affected by the disorder. Hence, the reduction of the magnetization results from the disorder in the directions of the local moments.

This is illustrated in Fig. 1 where we show the distributions of angles of the absolute values $|\mu_i|$ of the local moments and the distribution of the orientations in the form of a polar diagram. Figure 2 shows the orientation of the spins in the form of a vector model. For $\text{YFe}_{11}\text{Mo}_1$, we find that most moments are concentrated along the z direction, only two $\text{Fe}(8i)$ moments are oriented almost perpendicular to the preferred direction. For $\text{YFe}_{10}\text{Mo}_2$, the moments fan out in a wide angle, but again we observe (in the polar diagram as well as in the vector model), a preference of some Fe moments for an orientation in a plane perpendicular to the direction of the global magnetization. This is even more pronounced in YFe_9Mo_3 (and Mo on the $8i$ sites only) where the eight $\text{Fe}(8i)$ moments lie in pairs in a plane perpendicular to the other Fe-spins which show only a slight canting from the easy axis. This is the classical solution for antiferromagnetic moments in an almost uniform field resulting from the other Fe atoms. YFe_8Mo_4 is again a simple collinear ferromagnet (That our figures still show some canting is an artifact: we start from a completely random spin-configuration and to arrange all spins exactly parallel would require extremely long computer runs). If one Mo-atom per formula unit is put on the $8j$ sites, the character of the spin-structure changes [Figs. 1(b) and 2(b)] completely: YFe_9Mo_3 now shows spin-glass-like behavior of the Fe-moments, whereas in YFe_8Mo_4 the Fe-moments are arranged in a plane perpendicular to the

z direction. Hence, the calculations show not only that the substitutional disorder can lead to the formation of noncollinear—in the extreme case almost spin-glass-like—spin-structures, it also indicates that the character of the anisotropy changes from uniaxial to planar with higher Mo-contents. In principle, the anisotropy can be calculated quantitatively by repeating the calculations in applied fields of varying strength and varying geometry. However, this will require a very high additional computational effort.

In summary, we have shown that the calculation of noncollinear magnetic structures is now possible even for very complex compounds with substitutional disorder and that this leads to deep insights into the physical mechanisms determining the composition-dependence of the magnetic properties of permanent-magnet materials. The noncollinearity has to be attributed to competing ferro- and antiferromagnetic exchange interactions. Further increase of x however reduces the degree of noncollinearity (note that for $x=4$, all $8i$ sites are occupied by Mo so that the structure is again ordered), and although the resulting magnetization is smaller than in the collinear calculations, it is still appreciably larger than the experimental values. If we assume that for $x \geq 3$ some Mo-atoms occupy also other Fe-sites ($8j$ or $8f$), the calculations predict an almost spin-glass-like magnetic structure for $x=3$, while for $x=4$ the disorder in the spin directions is again reduced. The calculated magnetization is now in very good agreement with experiment.⁸ At the same time, the calculated spin-structures indicate that around $x \sim 2$, the character of the anisotropy changes from uniaxial to planar. This would confirm recent experimental observations.^{10,11}

Long range order in 2-D arrays of nanometer-sized Fe islands on $\text{CaF}_2/\text{Si}(111)$ (invited) (abstract)

M. R. Scheinfein, K. E. Schmidt, K. R. Heim, and G. G. Hembree

Department of Physics and Astronomy, Arizona State University, Tempe, Arizona 85287-1504

The effective magnetic moment was measured as a function of Fe island size during the initial stages of Fe growth on $\text{CaF}_2/\text{Si}(111)$ in an ultrahigh vacuum scanning electron microscope equipped with an *in situ* SMOKE analysis chamber. This substrate was selected for its wide bandgap, chemical inertness, viability of integration into an Si based technology and the availability of nanopatterning using electron beams for producing devices. Fe grown at room temperature initially nucleates into a monodisperse distribution of 3-D islands at very high nucleation densities ($8 \times 10^{12}/\text{cm}^2$). Increased Fe coverages lead to 2-D island growth. A room temperature superparamagnetic to ferromagnetic phase transition occurs as a function of Fe island radius. Mean field and Monte Carlo calculations illustrate that three distinct magnetic phases exist as a function of island diameter. Ferromagnetic order is present at room temperature when $r > 3$ nm, superparamagnetism is favored when $2 \text{ nm} < r < 3 \text{ nm}$, and a frustrated random antiferromagnetic phase exists when $r < 2$ nm. Further depositions of Ag on superparamagnetic Fe island arrays produce Ag islands which couple the covered Fe island moments in-plane, implying that the Ag mediates the magnetic exchange between individual Fe islands within an Ag island. Implications for 2-D giant magnetoresistance devices will be discussed. © 1996 American Institute of Physics. [S0021-8979(96)62908-7]

Fabricating nanoscale magnetic mounds using a scanning probe microscope

K. Bessho, Y. Iwasaki, and S. Hashimoto

Sony Corporation Research Center, 174 Fujitsuka-cho, Hodogaya-ku, Yokohama 240, Japan

Nanometer-scale mounds were fabricated by applying voltage pulses between a substrate and an atomic force microscope cantilever coated with magnetic material. Mounds were formed on both insulator and conducting substrates. Magnetic force microscopy (MFM) observations of the fabricated mounds were performed, and the contrast was turned over by reversing the magnetization of the tip, which is convincing proof that the mounds are magnetic. The MFM images also suggest that the mounds are perpendicularly magnetized. These results demonstrate that scanning probe microscope based nanofabrication is a promising method to fabricate nanoscale magnetic dots on any kind of substrates. © 1996 American Institute of Physics. [S0021-8979(96)40008-2]

I. INTRODUCTION

Magnetic thin films, magnetic thin wires, and magnetic fine particles, which are expected to show quite different intriguing properties from the bulk material, are now being actively investigated. Especially, periodic arrays of isolated single domain ferromagnetic mounds are of technological as well as scientific interest because they represent a possible future ultrahigh density recording medium.¹ To obtain such an array, it is necessary to reproducibly fabricate mounds which are only a few tens of nanometers in size. However, the preparation of such an array with well-controlled size and spacing is much more difficult than for example thickness control of thin films with molecular beam epitaxy.

Several methods have been presented, such as electron beam lithography,² islandlike growth of thin films,³ and scanning probe microscope (SPM) based nanofabrication.⁴ SPM based methods have the advantage that sufficiently small mounds can be fabricated and their positions can be controlled. We have already reported controlled fabrication of metallic PtIr mounds in air by field evaporation of material from a scanning tunneling microscope (STM) tip.⁵ In the present work we applied this method to fabricate an array of nanoscale magnetic mounds.

In general, magnetic materials are not favorable for a STM tip in air, because they are easily oxidized which causes the tunneling current to be unstable. An alternative idea is to perform the fabrication in an ultrahigh vacuum (UHV) chamber, or invoke an atomic force microscope (AFM), which does not require the tunneling current in the servo system.

In this work, we focus on the fabrication of magnetic mounds with AFM. The mounds were characterized with magnetic force microscopy (MFM).

II. PROCEDURE AND RESULTS OF MOUND FABRICATION

The AFM based nanofabrication was carried out in ambient conditions by applying voltage pulses between a metal coated AFM cantilever and a substrate, following Imura *et al.* who fabricated Au mounds reproducibly on the Si/SiO₂ substrate.⁶ We used a Digital Instruments' (DI's) MultiMode AFM (Nanoscope III), both in contact mode and in

TappingModeTM.⁷ Commercial Si cantilevers, sputter coated with CoCr by DI, which were originally for MFM observation, were used in the expectation that coated CoCr should be field evaporated and deposited onto the substrate. The spring constant of the CoCr coated cantilevers was around 5 N/m. Co or Fe were evaporated on the MFM cantilevers, which were also used in order to fabricate Co and Fe mounds.

Both insulators and metals were used as substrates. The insulator was a piece of Si wafer with a chemically oxidized SiO₂ layer on the surface (Si/SiO₂ substrate), which was prepared by boiling in acid (the usual 4:1:1 mix of water, peroxide, hydrochloric acid) after removing the native oxide layer in hydrofluoric acid. The thickness of the SiO₂ layer is estimated to be 2 nm by ellipsometry. The metal substrates will be described later.

Figure 1 shows mounds fabricated using (a) CoCr coated, (b) Co coated, and (c) Fe coated cantilever, by applying (a) -7 V, 0.5 ms, (b) -8 V, 0.5 ms, and (c) -9 V, 0.5 ms pulse voltage to the Si/SiO₂ substrate. (a) and (b) were done in contact mode, and (c) in TappingMode. The diameter and the height of the fabricated mounds were about (a) 70 and 10 nm, (b) 140 and 5 nm, and (c) 175 and 55 nm, respectively. These mounds are expected to be composed of coated magnetic material emitted from the cantilever surface toward the substrate by field evaporation.

Figure 2 shows an array of mounds fabricated by repeatedly applying +12 V, 900 ms pulses to a Si/SiO₂ substrate using a CoCr coated cantilever. In this way, nanometer scale mounds were fabricated reproducibly using an AFM cantilever coated with magnetic material.

III. MFM OBSERVATION OF THE MOUNDS

We used MFM (in dynamic mode, Nanoscope III) to confirm that the fabricated mounds are really composed of magnetic material. In dynamic-mode MFM the shift of a cantilever resonant frequency due to the magnetic dipole interaction is detected, but the observation of this interaction is often impeded by other external force such as the resistance by the atmosphere, so-called air damping. We carried out the observation in low pressure (500 mTorr) in order to reduce this air damping, because this noisy effect is liable to stand

FIG. 1. Mounds fabricated using a (a) CoCr coated, (b) Co coated, and (c) Fe coated cantilever, by applying (a) -7 V, 0.5 ms, (b) -8 V, 0.5 ms, and (c) -9 V, 0.5 ms pulse voltage to the Si/SiO₂ substrate [500 nm \times 500 nm scan for (a), 750 nm \times 750 nm scan for (b) and (c)]. The diameter and the height of the fabricated mounds were about (a) 70 nm and 10 nm, (b) 140 and 5 nm, and (c) 175 and 55 nm, respectively.

out in observing a steep mound around its foot. A new CoCr coated MFM cantilever, with spring constant $k=5$ N/m and resonant frequency $f_0=67$ kHz, was used.

Figure 3(a) shows an AFM image of mounds fabricated with a Co coated cantilever. The diameter and the height of the upper mound is 300 and 60 nm, respectively. Figure 3(b) shows the MFM image of the mounds observed simultaneously with the AFM image. The MFM cantilever (tip), which had been magnetized in the bottom-to-apex direction in about 3 kOe field using a permanent magnet, was lifted 100 nm during observation. After being taken off from the MFM unit and magnetized in the opposite direction with the permanent magnet again, the tip was used to observe the interaction with the same mounds, as is shown in Fig. 3(c). The contrast for the MFM image has been turned over by reversing the direction of the tip magnetization, which is a convincing proof that the interaction between the tip and the mounds is actually magnetic.

Figure 3 also suggests that the mounds are perpendicularly magnetized. The contrast by the mounds and the substrate was estimated to be a 3.6° shift in phase of cantilever vibration, and corresponds to the interaction force gradient $\partial F_z/\partial z = 3.0 \times 10^{-3}$ N/m. A simple calculation to estimate the interaction force gradient was also carried out using MathematicaTM. To represent the tip magnetization, a $(50$ nm)³ cubic magnet magnetized perpendicular to the substrate was assumed at the position of the tip apex, for the thickness of CoCr is around 50 nm.⁷ Recorded bits on Co/Pt multilayer film were observed in order to estimate the tip magnetic mo-

FIG. 2. An array of CoCr mounds on a Si/SiO₂ substrate (550 nm \times 550 nm scan). Each mound was fabricated by applying a voltage pulse of $+12$ V for 900 ms. The size of a mound is typically 40 nm in diameter and 2 nm in height.

FIG. 3. (a) An AFM image of mounds fabricated with Co coated cantilever (750 nm \times 750 nm scan). The diameter and the height of the upper mound is 300 and 60 nm, respectively. (b) A MFM image of the mounds observed simultaneously with the AFM image, taken with a new CoCr cantilever magnetized in the bottom-to-apex direction. (c) A MFM image of the mounds observed simultaneously with the AFM image, taken with a cantilever magnetized in the apex-to-bottom direction.

ment, and 2.44×10^{-22} Wb m was obtained by comparing the contrast from the MFM image and the calculation using the saturation magnetization $M_s=0.5$ T, the thickness $t=18$ nm and the diameter of the bit $d=3000$ nm for the Co/Pt film. With these data, the calculation based on the integral of magnetic dipole interaction between small volume elements in a perpendicularly magnetized Co mound and in the cubic tip resulted in $\partial F_z/\partial z = 2.3 \times 10^{-3}$ N/m, which is quite comparable to that obtained in the actual observation. If we assume that the mounds are magnetized in-plane, the estimation of the force gradient resulted in values 10 times larger than in the perpendicular case. Therefore, this is further evidence that the mounds are magnetized perpendicularly.

IV. MOUND FABRICATION ON A METALLIC SUBSTRATE

In addition to insulator (Si/SiO₂) substrates, mounds were fabricated on metallic substrates by two different methods. One is to apply pulses in TappingMode AFM, so that the electric field can be generated when the cantilever is not touching the surface. A piece of Pt wire was melted and

FIG. 4. The fabricated mounds on a Pt (111) substrate by repeatedly applying $+13$ V 500 ms pulses to the substrate with TappingMode AFM (350 nm \times 350 nm scan). The size of a mound ranges 40 – 50 nm in diameter and 3 – 10 nm in height.

FIG. 5. An array of mounds fabricated by repeatedly applying +2.1 V, 0.3 ms pulses to the Pt thin-film substrate (300 nm \times 300 nm scan). The size of a mound ranges 10–40 nm in diameter and 3–25 nm in height.

cooled to give a Pt ball with (111) facets on its surface, a chosen facet of which was used as a conducting substrate.

Figure 4 shows the fabricated mounds on a Pt (111) substrate by repeatedly applying +13 V, 500 ms pulses to the substrate.

Another way is to apply pulses between a STM tip and a substrate in UHV, as mentioned in the introduction. Much purer mounds are expected in this method. The fabrication was performed in vacuum less than 5×10^{-10} Torr at room temperature. The STM was a commercial one (Unisoku USM-501) and tips were made of electrochemically etched 0.25 mm diam Ni wire. The substrate was epitaxial Pt thin film evaporated onto MgO (100) single crystal. After pulsing, the substrate surface was observed again with the same tip.

By repeatedly applying +2.1 V, 0.3 ms pulses to the substrate, an array of mounds were fabricated as shown in

Fig. 5. The diameter of the mounds was in the range 10–40 nm, which is sufficiently small to be a single domain particle.

V. SUMMARY

Nanoscale mounds of CoCr, Co, or Fe were fabricated on the Si/SiO₂ substrate using AFM based nanofabrication techniques. Using TrappingMode AFM or UHV-STM, mounds of CoCr or Ni were also formed on a conducting platinum substrate.

MFM observations of the fabricated Co mounds were performed. The contrast was turned over by reversing the magnetization of the tip, which is a convincing proof that the mounds are indeed magnetic. The MFM images also suggest that the mounds are perpendicularly magnetized. These results demonstrate that SPM based nanofabrication is a promising method to fabricate nanoscale magnetic dots on any kind of substrate.

Behlen Laboratory of Physics and Center for Materials Research and Analysis, University of Nebraska, Lincoln, Nebraska 68588-0111

We have prepared nanometer-size, isolated CoPt particles. The particles in the range of 100–300 nm in diameter were formed by annealing thin films in the temperature range of 550–800 °C. Films with magnetic coercivity as high as 30 kOe were achieved. The results indicate that the high magnetic coercivity was obtained because the crystallite size approaches that of noninteracting single-domain particles. © 1996 American Institute of Physics. [S0021-8979(96)04508-3]

I. INTRODUCTION

One of the requirements for practical applications of magnetic devices, such as high-density magnetic recording media, magnetic bias films of magneto resistive elements, and magnetic tips for magnetic force microscopy, is high magnetic coercivity (H_c).^{1,2} It is known that an assembly of very fine noninteracting high anisotropy magnetic particles is magnetically hard; i.e., it has a large coercivity. This effect is due to the fact that the particles are single domains and that magnetization reversal takes place only by rotation of M_s vectors against strong anisotropy forces. For randomly distributed single-domain particles, the H_c will be as high as $0.98K/M_s$, where K is the anisotropy constant and M_s is the saturation magnetization.³

The CoPt binary alloy is an excellent system because it has both chemical stability and high magnetic anisotropy. CoPt alloy thin films have received significant attention as possible magneto-optic recording media owing mainly to the existence of ordered intermetallic phases with exceptional magnetic properties.^{4,5} CoPt compounds are known for their hard magnetic properties. In the bulk form, it shows a high magnetocrystalline anisotropy (4×10^7 ergs/cm³) and a relatively large saturation magnetization $M_s = 800$ emu/cm³.^{6,7} From the calculation using the above equation, one would expect an H_c of 48 kOe in the CoPt alloy. However, early studies showed H_c values of less than 6 kOe in a CoPt binary alloy.^{6–8} Recently, Qiu *et al.* have shown that a maximum intrinsic coercivity of about 4.3 kOe was obtained in a mixture of ordered and disordered phases after annealing the rapidly solidified CoPt alloy at 700 °C for 30 min.⁹ In thin films, as reported by Tsoukatos *et al.* the maximum H_c observed in CoPt films is of the order of 6.8 kOe.¹⁰ It is known that the hard magnetic behavior of the CoPt alloy is related to the crystal phase transition. The as-cast alloy has a disordered fcc structure which transforms into an ordered fct structure with $c/a = 0.98$ after annealing at a temperature below 835 °C. The magnetic hardness of permanent magnets are also influenced by the size of the particles and the interaction between the particles. In order to have a better understanding of magnetic properties of small particles in the CoPt

alloy system, we need to prepare films which consist of desired nanostructures.

In this paper, we report a method to prepare films containing nanometer-size particles and show the development of coercivity as high as 30 kOe in CoPt alloy films.

II. EXPERIMENT

The CoPt alloy films were prepared on fused quartz substrates with dc magnetron sputtering. The film thickness was in the range of 10–300 nm. The substrate was fused quartz. The target was made by sintering high-purity Co (99.9%) and Pt (99.99%) powder with 1:1 atomic ratio at 1050 °C for 24 h. The base pressure before introducing the Ar gas was 3×10^{-8} Torr. In order to improve the ordering and to control the crystallite size, the CoPt films were annealed under one atmosphere of Ar/H₂ in the temperature range of 550–800 °C, and the range of annealing time was from 30 min to 40 h. The magnetic properties of the films were measured by SQUID magnetometry. The crystal structure and particle sizes were examined by high-resolution transmission electron microscopy (HRTEM), selected-area diffraction (SAD), nanodiffraction, and atomic force microscopy (AFM).

III. RESULTS AND DISCUSSION

Particle growth on a substrate is dependent on the strength of interaction between the atoms of the growing film and the atoms of the substrate. As shown by Pashley, particles as small as 10 nm can be formed in the early nucleation stage.¹¹ If we choose suitable substrates and growth conditions, CoPt films with well separated particles can be produced. One would expect that particles in the range of 10–500 nm can be prepared by controlling the thickness of films and substrate temperatures.

In this study, we prepared CoPt films with the thickness of 10, 20, and 320 nm on quartz substrates and then annealed them in the temperature range of 550–800 °C. Most metals do not wet insulating surfaces such as quartz, so that the particles are expected to form after the thermal treatment.

As shown in Fig. 1, the H_c of CoPt films is in the range of 2–22 kOe, depending on the film thickness and annealing

FIG. 1. The evolution of H_c vs the annealing temperature for films with thickness of 10, 20, and 320 nm.

temperature. These films were annealed in the temperature range of 550–800 °C for 30 min in Ar/H₂ atmosphere. The H_c was measured at 300 K with the film surface perpendicular to the magnetic field. The as deposited films regardless of their thickness has a H_c less than 100 Oe. The H_c increases with the increasing annealing temperature. The highest H_c of 22 kOe was observed for 10-nm-thick films annealed at 750 °C. For films annealed at 800 °C, the value of H_c decreased. The H_c of the film with a thickness of 320 nm after annealing at 800 °C also decreased. This datum is not shown in Fig. 1, because it was not prepared in the same sputtering run.

In the CoPt binary system, a disordered fcc and a tetragonal CuAu type structure can coexist in the concentration near 50 at. % Co. This system exhibits excellent hard magnetic properties that depend strongly on the concentration and the degree of crystalline order of the alloy.

As shown in Fig. 2, HRTEM images show that all the as-deposited CoPt films are continuous and composed of 5–10 nm crystallites. The corresponding SAD ring pattern can be indexed using a disordered fcc structure model. After annealing at 750 °C, the crystal structure of the films transforms to the fct structure as identified by the nanodiffraction. The 320-nm-thick film remains continuous after annealing and has crystallite sizes of 50–100 nm. For films of nominal thickness on the order of 10 nm, the alloy forms 50–300 nm particles which grow discontinuously on the substrate. Dark-field images show that there are several crystallites in the large particles. The particles are clearly observed by using atomic force microscopy. As shown in Fig. 3, the CoPt film with a thickness of 10 nm after annealing at 750 °C for 30 min formed many particles with a size range of 50–300 nm. The particle height is in the range of 30–70 nm. This indicated that the film area near the particle was cleaned during the formation of particles.

The observed microstructure is consistent with the early studies that the formation of the tetragonal crystallite and the growth of the crystallite after annealing at high temperature is partly responsible for the increase of H_c .^{8–10} It is known that the film annealed at high temperature increases the size of the crystallite which is clearly observed in HRTEM image.

FIG. 2. (a) HRTEM image of as-deposited film. (b) Dark-field image for film annealed at 750 °C for 30 min.

For films annealed at 800 °C, the reduction of H_c may be due to the further crystallite growth which results in the formation of multidomain. In comparison with earlier studies, one of the major differences is possibly that the particle size and the interaction between the particles in these samples prepared by different groups are not the same. In our films, the separated nanometer size particles form a nearly non-interacting system which leads to very high H_c values. This conclusion is also supported by our thickness dependence of the H_c in the films which were prepared from the same sputtering run and annealed together at the same temperature and time duration. Under this preparation condition, the ordering and the size of the crystallite in these films should be the same. One of the major differences between the thin and the thick films is the separation of the particles, i.e., the interactions between the particles is not the same as in these films when they have different thickness. As shown in Fig. 1, the value of H_c of the 10-nm-thick film is about two times higher than that of the 320-nm-thick films.

In order to further understand the effect of the ordering on the H_c , we have examined a series of samples with 10 nm thickness which were annealed at 750 °C for 30 min to 40 h.

FIG. 3. The atomic force microscopy picture of a nominal 10-nm-thick CoPt film annealed at 750 °C for 30 min.

The result is shown in Fig. 4. The magnetic coercivity of CoPt films dramatically increases upon annealing at 750 °C for 3 h, and then decreases to roughly 24–25 kOe after 20 h annealing. The hysteresis loop of the film with the highest H_c measured at 300 K is shown in Fig. 5. The measured intrinsic coercivity in this film is 30 kOe. Here we should note that the measured value may not be the actual H_c due to the low applied magnetic field (5.5 T). The ordering of the crystallites should improve after a long annealing time, so the H_c of the film should also improve if the ordering is the most important factor. The reduction and the leveling off of the H_c in the films after long annealing indicates that the crystallite growth is more important than the further ordering in these films. The increase of H_c at the beginning of the

FIG. 4. The H_c of CoPt films with a nominal 10 nm thickness annealed at the temperature of 750 °C for 30 min to 40 h.

FIG. 5. The hysteresis loops of a CoPt film with a nominal 10 nm thickness that was annealed at 750 °C for 3 h.

annealing stage is likely due to the growth of the crystallites which reach the size of a magnetic single domain. After further annealing, the drop in H_c of the films may be due to the increase in the crystallite size which results in multidomain formation.

IV. SUMMARY

As revealed by high-resolution transmission electron microscopy and atomic force microscopy, we have prepared well separated and nanometer-size CoPt particles (in the range of 100–300 nm). The smaller particles form a nearly noninteracting system and have dimensions close to the single-domain particle size which leads to a very high coercivity value of about 30 kOe. This value is about five times higher than the early studies which show coercivity values of less than 6 kOe and is close to the theoretical estimate of 48 kOe for the CoPt alloy.

Oxidation states and magnetism of Fe nanoparticles prepared by a laser evaporation technique

B. J. Jönsson, T. Turkki, V. Ström, M. S. El-Shall,^{a)} and K. V. Rao
Royal Institute of Technology, Department of Condensed Matter Physics, 100 44 Stockholm, Sweden

Nanoparticles of iron and iron oxide have been prepared in a thermal diffusion cloud chamber using pulsed laser evaporation. SEM/TEM studies of these particles reveal a size distribution with a mean diameter of about 60 Å. This is consistent with the mean particle size estimated from the magnetic data. The oxidation levels of these nanoparticles prepared at different partial oxygen pressures were investigated using FTIR. All the samples are found to exhibit superparamagnetism with blocking temperatures ranging from 50 K to above room temperature. Magnetic anisotropy constants are calculated from the frequency dependence of the blocking temperatures are found to be one quarter of magnitude higher than is known for the bulk. © 1996 American Institute of Physics. [S0021-8979(96)40108-1]

I. INTRODUCTION

Ultrafine or nanoparticles have been the subject of intense research in recent years. Nanoparticles have unique properties in comparison with the bulk: large surface to volume ratio, discrete electron energy levels which can be easily tuned over a wide range of compositions, etc. Magnetic nanoparticles become single domain below a certain size and exhibit superparamagnetism. Interest in magnetic nanoparticles remains high because of the wide range of potential applications, including information storage, ferrofluids, permanent magnets and pigments in paints. Iron oxide nanoparticles are also expected to have properties as high performance catalysts.

In this paper, we present the magnetic properties of iron and iron oxide nanoparticles produced by pulsed laser evaporation in different oxygen partial pressure atmosphere. The superparamagnetic properties of these nanoparticles are also presented.

II. EXPERIMENT

Iron oxide samples were prepared in a modified upward thermal diffusion cloud chamber.^{1,2} A sketch of the chamber is shown in Fig. 1. The iron target was set on the bottom plate. The chamber was filled with desired amount of oxygen and further filled with helium to 800 Torr. The top plate was cooled down to -100 °C while the bottom plate was at room temperature. Metal was vaporized using Nd:YAG laser (532 nm, 20 Hz, and 20 mJ/pulse). In the present investigations the partial oxygen pressure was varied from 0 to 500 Torr while keeping the total pressure at 800 Torr.

SEM and TEM micrographs were taken with JEOL SM 840 and JEOL 2000 EX instruments, respectively. The infrared absorption spectra were recorded on a Nicolet 750 Magna Fourier transform spectrophotometer under atmospheric pressure. dc magnetic measurements were performed using Quantum MPMS₂ SQUID magnetometer. The zero field cooled measurements were performed by cooling the sample to 5 K at zero field and then applying 20 G field for

the warming up scan. Hysteresis loops were measured at selected temperatures. Between every loop the sample was warmed up to 300 K and the remanence field was minimized. ac magnetic measurements were performed using a home-built two-position ac susceptometer with a three-coil mutual inductance bridge. The driving field was 3 Oe for all measurements and the frequency was varied from 4 Hz to 4 kHz.

III. RESULTS AND DISCUSSION

For brevity we label the samples Fe-0, Fe-10... allowing the number to denote the partial oxygen pressure, in Torr, during preparation. The color of the samples goes from very dark brown, almost black (the color of FeO and Fe₃O₄) to reddish brown (the color of γ -Fe₂O₃) with increasing oxygen pressure. TEM bright field images (Fig. 2) show the samples to consist of very small particles with mean diameter of about 60 Å. Some larger particles with sizes 50–500 nm are also present. No significant difference in particle size distribution is observed between different samples. The size of the particles is found to be controlled by the total pressure, temperature gradient, and the partial pressure of the metal vapor. These parameters were kept the same for every preparation. The diffuse TEM electron diffraction patterns indicate the presence of FeO, Fe₃O₄, and γ -Fe₂O₃ phases in all samples.

Because of the high surface to volume ratio the activity at the surface of the nanoparticles would be significantly different from that of the bulk. From the Fourier transformed, FTIR absorption data we find that in these particles the chemisorption of CO₂ increases with the partial oxygen pressure. At oxygen partial pressures below 200 Torr the samples are found to consist mainly of Fe₃O₄ with some γ -Fe₂O₃ contamination. The γ -Fe₂O₃ peak at 450 cm⁻¹ is barely visible. At higher partial oxygen pressures the sample stoichiometry appears to be close to the γ -Fe₂O₃ form.

The iron and iron oxide particles prepared in this study, have sizes within the single domain particle regime (about 200 Å for Fe). Their magnetic behavior is well described in terms of superparamagnetism. For a superparamagnet the relaxation time τ is given by.³

$$\tau = \tau_0 e^{KV/k_B T}, \quad (1)$$

^{a)}Permanent address: Virginia Commonwealth University, Department of Chemistry, Richmond, VA 23284-2006.

FIG. 1. A sketch of the diffusion cloud chamber.

where K and V are the anisotropy constant and the particle volume, respectively, and τ_0 is of the order of 10^{-9} s. The superparamagnetic behavior is observed above the blocking temperature T_B . Below T_B the particles are magnetically frozen and hysteresis appears.

The in-phase ac susceptibility χ' was measured for five samples prepared at different partial oxygen pressures (Fig. 3). χ' is found to increase monotonically with temperature for the Fe-0 sample. This behavior is consistent with expected blocking temperature⁴ of 300 K for iron particles in the size range 60–80 Å. When the particles consist of iron oxide instead of iron, there is a dramatic change in behavior. A clear cusp is seen at about 65 K in sample Fe-10. Increasing the oxidation of iron, as in Fe-50, gives rise to another cusp around 110 K which then dominates in Fe-200. Finally, we observe only one cusp in the Fe-500 sample.

There is a sudden increase in coercivity below the blocking temperature (Fig. 4). The coercivity does not fall to zero above T_B as expected for a purely superparamagnetic sample. This is probably due to the existence of the few large-size particles (50–500 nm) seen in the TEM micrographs.

The magnetization of a paramagnet follows a Langevin function:

FIG. 3. In-phase ac susceptibility as a function of temperature.

$$\frac{M}{M_s} = L(a) = \coth a - \frac{1}{a}, \quad a = \frac{\mu H}{k_B T}. \quad (3)$$

Since the Langevin function is a linear function for small arguments, $L(a) \approx a/3$, this will hold for superparamagnetic particles of different sizes at low fields. Thus, measuring M/H loops and taking the slope around zero field gives us a means of calculating the mean-magnetic moment of our particles and therefore, a mean-particle diameter.

The mean-magnetic moment per particle for sample Fe-10 is found to be $5100 \mu_B$. Assuming the dominant phase to be Fe_3O_4 , which has $4.1 \mu_B$ per molecule, eight molecules per unit cell and a lattice constant of 8.39 Å, we estimate the mean-particle diameter to be around 60 Å, in good agreement with the TEM observations.

Knowing the mean volume of our particles we can now estimate K_1 . We measured χ' at six different frequencies between 4 and 4000 Hz and included a SQUID measurement with a measuring time of about 100 s. Taking the maximum of χ' to be the blocking temperature and plotting $1/T_B$ vs $\ln(f)$, f being the driving frequency, we get a straight line (Fig. 5). The slope of this line is equal to $-k_B(|K_1|/V)^{-1}$, according to Eq. (1).

FIG. 2. TEM micrograph of the Fe-10 sample.

FIG. 4. Coercivity field as a function of temperature for samples showing one single cusp.

FIG. 5. Plot showing the blocking temperature as a function of measuring frequency for samples Fe-10 and Fe-500.

In the case of a cubic structure with the easy direction along $\langle 111 \rangle$, K_1 is replaced⁵ by $K_1/12$. We thus get an anisotropy constant $|K_1| = 2.1 \times 10^6$ ergs/cm³ for sample Fe-10. If we assume the mean size to be equal in all samples we get $|K_1| = 3.1 \times 10^6$ ergs/cm³ for the sample Fe-500. Those values for $|K_1|$ are an order of magnitude larger than the values for bulk Fe₃O₄ and γ -Fe₂O₃, but agrees well with values reported in literature⁶ for small particles.

Since all samples have about the same size distribution it is the difference in composition that determines the different magnetic behavior. The sample Fe-0 has a high blocking temperature due to the anisotropy barrier being higher for iron than for its oxides. In iron the easy directions are along the cube sides $\langle 100 \rangle$ and K_1 should be replaced by $K_1/4$ and not $K_1/12$. When the core of the nanoparticles is Fe₃O₄ the anisotropy barrier is reduced and the blocking temperature falls to about 50 K. With increasing oxidation, the fraction of γ -Fe₂O₃ increases and since its anisotropy barrier is slightly higher than that for Fe₃O₄, a new cusp develops at about 110

K. As the γ -Fe₂O₃ fraction further increases this cusp dominates and is the only one observed in the sample Fe-500.

IV. CONCLUSIONS

We have demonstrated a simple technique to prepare nanoparticles of iron and iron oxide. By varying the partial oxygen pressure in preparation we have been able to change the oxidation state of Fe. Particles prepared at low oxygen pressure consist mainly of FeO and Fe₃O₄ while those prepared at higher oxygen pressure consist of γ -Fe₂O₃. As a consequence the magnetic behavior changes in a rather complex way. The magnetic properties, analyzed in terms of superparamagnetism, are found to be consistent with the implications from the particle size and structure. Magnetic anisotropy constants calculated from our experimental data agree well with the expected values for small particles.

65 Gbits/in.² quantum magnetic disk (abstract)

Stephen Y. Chou and Peter R. Krauss

NanoStructure Laboratory, Department of Electrical Engineering, University of Minnesota, Minneapolis, Minnesota 55455

Quantum magnetic disk (QMD), proposed recently, offers a new paradigm for ultrahigh density magnetic recording.¹ In a QMD, each bit is represented by a prepatterned nanoscale single-domain magnetic pillar or bar that was uniformly embedded in a nonmagnetic material on a disk. The size and shape of each bit is well controlled during the fabrication to ensure single magnetic domain formation, therefore the magnetic moment of each bit has only two quantized states: equal in magnitude but opposite in direction. Compared to conventional magnetic disks, the QMD offers many unique advantages in writing, reading, and tracking. In this article, we report the fabrication of both longitudinal and perpendicular magnetization QMDs and their investigation with scanning electron microscopy, atomic force microscopy, and magnetic force microscopy. Both QMDs were fabricated using electron beam nanolithography, reactive ion etching, and chemical mechanical polishing. We will also discuss QMD fabrication techniques which do not involve conventional lithography. The perpendicular QMD structure consists of 50-nm-diam nickel pillars uniformly embedded in 200 nm thick SiO₂ with a surface roughness of 0.5 nm rms. The pillar array has a period of 100 nm which corresponds to a magnetic storage density of 65 Gbits/in.²—over two orders of magnitude greater than the current state-of-the-art magnetic storage density. © 1996 American Institute of Physics. Quantized writing processes in quantum magnetic disks (abstract)

Usman Suriono and Stephen Y. Chou

NanoStructure Laboratory, Department of Electrical Engineering, University of Minnesota, Minneapolis, Minnesota 55455

It has been suggested that the writing process in quantum magnetic disks (QMDs) is quantized: a write head either writes perfectly the entire bit which is a discrete single-domain element isolated from other bits with nonmagnetic materials, or it does not write the bit at all.¹ This article presents the micromagnetics demonstration of this quantized writing process. In the simulation, each QMD bit is assumed to be a polycrystalline cobalt bar of 700 nm long, 50 nm wide, and 30 nm thick, and to be oriented parallel to the disk surface. To obtain the dynamic motion of the magnetization structure of the bit, iterative energy minimization algorithm and the Landau–Lifshitz–Gilbert equation were used. The write head field is assumed to be parallel to the long axis of the bar and uniform with a strength of 2.5 times the bar coercivity. The write field has a width the same as that of the bar but a length that is only three-quarters of the cobalt bar length. It was found that even though the writing field size was smaller than the size of the bar, the magnetic moment of the entire single-domain bar can be switched from one direction to another, giving a perfect writing. The switching process occurred roughly in two stages. First, the magnetic moments got reversed in the region where the write field was applied. Second, driven by exchange force and shape anisotropy, the reversal propagated out of the write field region and reached the entire bit. It was also found that if the overlap of the writing field with the bar was less than one-quarter of the bar length in the bar long axis or four-fifths of the bar width in the bar short axis, the writing field would only temporarily perturbs the magnetic moment distribution of the bar. When the write field was removed from the bar, the magnetic moment of the bar would return to its original state. The quantized writing process in the QMD will allow the use of a smaller and therefore faster write head, can avoid the errors due to misplacement and fringing field, hence is suitable for ultrahigh-density storage. © 1996 American Institute of Physics. Nonmonotonic length dependence of switching field of nanolithographically defined single-domain nickel and cobalt bars (abstract)

Linshu Kong and Stephen Y. Chou

NanoStructure Laboratory, Department of Electrical Engineering, University of Minnesota, Minneapolis, Minnesota 55455

Previously, the switching field of nanolithographically defined single-domain permalloy and nickel bars was found to increase monotonically as the bar aspect ratio increases¹ or as the bar width decreases.² In this work, we will show, for the first time, that when the bar width is fixed, the switching field of nanolithographically defined single-domain nickel and cobalt bars changes nonmonotonically with the bar length (hence the aspect ratio). The isolated Ni and Co bars were fabricated using electron-beam lithography and a lift-off process, and have a thickness of 35 nm, a fixed width of 100 nm, and a length varying from 200 nm to 5 μm . The magnetic force microscopy (MFM) showed that all the as-fabricated bars, except for the Ni bars with a length less than 500 nm, are single domain. The switching field of the single-domain bars was found to increase with the bar length first, then decrease after reaching a peak. The peak switching field and corresponding bar length are 640 Oe and 1 μm for Ni, and 1250 Oe and 2 μm for Co. This behavior, which clearly deviates from Stoner-Wohlfarth model, suggests that two different mechanisms should be responsible for the magnetization reversal process in different bar lengths. When the bar length is small, the exchange energy can be much larger than the magnetostatic energy to keep the bar switching quasicoherently and the switching field increases with the bar length. However, when the bar length is large, the exchange energy cannot overweigh the magnetostatic energy for quasi-coherent switching and therefore the lowest switching energy state would be incoherent switching which involves multidomain (or vortex) reversal leading to an decrease of switching field. The detailed analysis will be presented in the paper. © 1996 American Institute of Physics. [S0021-8979(96)82208-4]

Ultramicro fabrications on Fe-Ni alloy films using electron-beam writing and reactive-ion etching (abstract)

I. Nakatani

National Research Institute for Metals, Tsukuba 305, Japan

Microfabrication techniques are successfully used for semiconducting materials, while they are limited for the application to magnetic materials. For the magnetic materials, useful RIE (reactive-ion-etching) process that is essential for high-resolution microlithography has not yet been successful. In this work, RIE method useful for permalloy (80%Ni-4.5%Mo-Fe) has been newly constructed. High-resolution electron-beam writing was followed by the RIE process, leading to 250 nm line and space patterns in the permalloy film with 10 nm accuracy. In order to achieve a high-resolution electron-beam writing, amorphous carbon film was use between the resist layer and SiO₂ film overlaid on the permalloy film. There are four levels in the process. Most critical step in the fabrication of magnetic material is RIE process using a rf discharged plasma of NH₃-CO mixed gas. Maximum etching rate of 35 nm/min and highly anisotropic etching for the permalloy was obtained at the composition of 50 mol % NH₃-CO at the pressure of 2.4×10^{-3} Torr. The etching selectivity ratio of permalloy to SiO₂ employed as a mask was about 10. By this method, nanostructures of permalloy with highly anisotropic profile were fabricated. This method shows prominent features still for Co-Cr alloy films. © 1996 American Institute of Physics. [S0021-8979(96)80608-X]

Structural and magnetic study of submicronic single crystal cobalt box arrays

We present a study of magnetic dot arrays fabricated in Ru(5 nm)/Co/Ru(32 nm) films with cobalt thickness varying from 10 to 500 nm. Large array areas up to $5 \times 5 \text{ mm}^2$ have been obtained with lateral dot size and spacing of $0.5 \text{ }\mu\text{m}$. The magnetization curves are characteristic of a perpendicular magnetized multidomain structure. Lateral size reduction does not drastically change the domain structure but has immediate consequences on the nucleation and saturation fields. A magnetic force microscopy study confirms the perpendicular multidomain structure and provides intrinsic magnetic characteristics. © 1996 American Institute of Physics. [S0021-8979(96)40208-1]

The magnetization orientation in Co films depends strongly on the film thickness. By growing ultrathin Co(0001) layers, the surface anisotropy, combined with the strong crystalline anisotropy, allows Co to retain its magnetization direction perpendicular to the film despite the large magnetostatic energy. Such perpendicular anisotropy has been clearly evidenced in several systems as Co/Au(111)¹ or Co/Ru(0001).² When the Co thickness is increased, the surface contribution is reduced and is not anymore sufficient to overcome the demagnetizing energy. Consequently, the magnetization lies in plane.

For thicker films, there must be one additional crossover predicted by Kittel³ for which the magnetization turns from in-plane to out-of-plane. This prediction based on a classical model taking into account the magnetic anisotropies, the dipolar energy and the energies of the boundary surfaces between domains foresees that the crossover thickness (t_{cr}) for which the magnetization turns out of plane is about 30 nm for a perfect hcp structure.⁴

The objective of our work is to favor a perpendicular single domain magnetization structure for large Co thicknesses by stabilizing a (0001) hcp cobalt structure which gives rise to a large perpendicular magnetocrystalline anisotropy ($K_{MC} = 5.2 \times 10^6 \text{ erg/cm}^3$). In this paper, we have identified the crossover thickness above which the magnetization is perpendicularly oriented in the domain structure. Moreover, we have determined the average domain size of the order of 100–200 nm. A possibility to quantify the domains density down to a limit for which the system behaves like a single domain structure would be to reduce the lateral dimensions below a critical length of the order of the domain size in the continuous film. Considering this idea, we have studied in this paper the relationships between the film thickness and the reduction of the geometric lateral dimensions on the magnetic properties and the domain structure.

Ru(5 nm)/Co(t_{Co})/Ru(20 nm) films with cobalt thickness (t_{Co}) varying from 10 to 500 nm were prepared by molecular-beam epitaxy at 400 °C on Al₂O₃ (11 $\bar{2}$ 0) substrates. The RHEED patterns obtained during the sample

growth reveal well-defined rods which suggest good crystalline quality. $\theta/2\theta$ x-ray diffraction scans of the (222)fcc/(0004) hcp Bragg peak revealed a peak located at the expected angle for the hcp stack.

Patterning was performed using synchrotron x-ray lithography in the L2M lithography station implemented on the Super-ACO storage ring. Large array areas up to $5 \times 5 \text{ mm}^2$ have been obtained with lateral dot size of $0.5 \text{ }\mu\text{m}$ and array periodicity of $1 \text{ }\mu\text{m}$. Details on the different processes can be found elsewhere.⁵

Magnetization measurements at room temperature were carried out in an alternating gradient force magnetometer with the field applied perpendicular and parallel to the substrate plane. Two types of magnetic behavior have been observed depending on the Co thickness as expected from the Kittel prediction.³ This allows to identify the crossover thickness t_{cr} at about 25 nm.

Below t_{cr} , for both films and arrays, the magnetization curves are characteristic of samples which have their magnetic moments confined along the film plane.⁴ In the parallel configuration, the introduction of reduced lateral dimensions change the shape of the curves: the saturation field H_s is larger for dots because domains must be expelled from the dot instead of moving through the film. This effect gives rise to a decrease of the curve slope before saturation.⁴ The increase of the saturation field results from the nonzero value of the in-plane component of the demagnetizing field in contrast with the continuous films. In the perpendicular configuration, the saturation field value of about 11.5 kOe for the 10-nm-thick Co film allows the evaluation of the magnetocrystalline anisotropy ($4.6 \times 10^6 \text{ erg/cm}^3$). This value confirms the good crystalline quality of the hcp cobalt phase.

Above t_{cr} , the magnetization curves, for both films and arrays, are characteristics of samples which have their magnetic moments perpendicular to the film plane (Figs. 1 and 2). This result is confirmed by the domain imaging. In the following, we will first present the results obtained on the continuous Co films and then discuss the consequences of the reduction of the lateral dimensions of the films.

FIG. 1. Perpendicular and parallel M - H curves for a 150-nm-thick cobalt layer. The values for which the saturation (H_s) and nucleation (H_n) fields have been estimated are indicated with the arrows.

Continuous cobalt films: In the perpendicular direction (Fig. 1), the experimental magnetization curves⁴ display shapes very similar to those computed for bubbles and stripes domain lattices⁶ which strongly suggests that the magnetization states of the films consist of magnetic domains with perpendicular magnetization. The M - H curve slope, from zero up to near H_s , remains constant and results from a competition between pressures acting on the wall. The saturation field H_s (respectively, nucleation field H_n) (as shown in Fig. 1) increases from 12.6 (respectively, 10.3) kOe for t_{Co} of 100 nm to 16 (respectively, 14.6) kOe for 500 nm as shown in Fig. 3. Such an increase is related to the variation of the demagnetizing factor with the film thickness. This is presumably due to changes of the interaction between the charges at both surfaces within each domain.

The singularity in the decreasing field shown in Fig. 1 indicates the nucleation of domain walls followed by the wall motion. In the parallel configuration, H_s increases with film thickness as shown in Fig. 3. Walls are not submitted to a magnetic pressure from the magnetic field, and in conse-

FIG. 2. Perpendicular and parallel M - H curves for a 150-nm-thick dot array.

FIG. 3. Perpendicular nucleation field H_n , perpendicular and parallel saturation field H_s vs cobalt film thickness.

quence a coherent rotation is responsible of the magnetization reversal. Along this hypothesis, the saturation field in the parallel orientation can be described by the expression $H_{s\parallel} = (2/M_s) \times (K_1 + 2K_2) - H_{d\perp}(t_{Co})$ where K_1 and K_2 are the first and second order magnetocrystalline anisotropies and $H_{d\perp}(t_{Co})$ is the perpendicular demagnetizing field. This expression derived for a single domain structure, shows that for a 500-nm-thick Co film, using $K_1 = 5.2 \times 10^6$ erg/cm³ and $K_2 = 1.6 \times 10^6$ erg/cm³ (Ref. 7) of the bulk cobalt, $H_{d\perp}(t_{Co})$ must be neglected to fit the experimental value of $H_{s\parallel} = 11.75$ kOe. These negligible $H_{d\perp}(t_{Co})$ values, compared to the demagnetizing field for perpendicular single domain films ($4\pi M_s$), arise from the presence of magnetic domains of sufficiently small aspect ratio favorable to decrease the demagnetizing field to values close to zero. As the film thickness decreases (Fig. 3), $H_{s\parallel}$ decreases due to a small increase of $H_{d\perp}(t_{Co})$.

The domain structure has been observed in zero field by magnetic force microscopy (MFM) using a Nanoscope III from Digital Instruments with a magnetic tip in the tapping/lift mode. Figure 5(a) shows a typical domain structure observed on an epitaxial Co thin film. The MFM image of a 100-nm-thick cobalt film shows a demagnetized domain pattern consisting of stripes of about 100 nm domain width. The black and white contrast are related to domains oriented antiparallel. We found regular 180° domains with the magnetization vector pointing along the surface normal. Moreover, a systematic study of the domain width (W) with the film thickness (t_{Co}) has shown a linear relationship between W^2 and t_{Co} .⁴

Cobalt dots array: The results obtained on the magnetic dots indicate that, by reducing the geometric lateral dimensions, the magnetic properties are strongly affected although the experimental magnetization curves measured for the dot arrays above t_{cr} are very similar to those one obtained for the continuous films (Fig. 2). One can expect that the magnetization structure has not drastically changed with the lateral size reduction. However, the major magnetic parameters as the coercive, saturation, and nucleation fields show strong differences.

FIG. 4. Perpendicular nucleation field H_n , perpendicular and parallel saturation field H_s vs cobalt dot thickness.

In the perpendicular geometry, the consequences of the lateral size reduction are immediate (Fig. 4): H_s (respectively, H_n) decreases from 8.8 (respectively, 6.7) kOe for t_{Co} of 50 nm to 6.2 (respectively, 4.5) kOe for 200 nm instead of increasing. This is related to the reduction of the perpendicular demagnetizing factor N_\perp , with the increase of the aspect ratio. For a perpendicular multidomain structure, the perpendicular $H_s(H_s^m)$ can theoretically be evaluated, for a thick dot, from $H_s^m = N_\perp M_s$ while, for a single domain structure, it is equal to $H_s^s = N_\perp M_s - (2K_1/M_s)$. The result of the numerical evaluation for a 500-nm-thick dot with a lateral size of 700 nm gives $H_s^s \approx 0$ (square loop) and $H_s^m = 7.3$ kOe. This last value, close to the experimental one (6.8 kOe), gives a first proof of the existence of domains in dots. The decrease of H_n can be related to the size of the first nucleated domain. As indicated previously, the width of the domain increases with the film thickness. Consequently, for thicker dots, the energy required for nucleating large domains will increase and therefore decrease H_n . This has been confirmed by the MFM study. Indeed, the domain structure, as shown in Fig. 5(b) for the 50-nm-thick dots array, consists of stripes and bubbles domains with a domain width ($W=70-75$ nm) very similar to the one observed on the continuous films.

In the parallel geometry, the saturation field increases from 7.1 kOe for t_{Co} of 50 nm to 13.3 kOe for t_{Co} of 200 nm.

FIG. 5. MFM image of a demagnetized (a) 100-nm-thick continuous cobalt film and (b) 50-nm-thick array of dots.

For a single domain structure, the saturation field is equal to $H_s = (2/M_s)(K_1 + (N_\parallel - N_\perp)M_s^2 + 2K_2)$ and should vary from 2 to 6 kOe for, respectively, 50 and 200 nm thicknesses. The large difference between the experimental and calculated values shows that N_\perp , affected by the domain structure (already discussed in the case of continuous films), is much smaller than in the case of the single domain structure while N_\parallel remains the same. The saturation field evaluated, in a first approximation using $N_\perp = 0$ gives a quite good agreement with the experimental data.

In summary, we have evidenced a crossover thickness at about 25 nm for epitaxial (0001) hcp cobalt films, above which the magnetization is perpendicularly oriented with a stripe and bubble domain structure. The MFM images have shown that the domain width of the stripes increases with the cobalt thickness. The lateral reduction of the cobalt films in dots of 500-nm-linewidth arrays have shown that the intrinsic magnetic characteristic have been strongly affected whereas the domain structure shows similar features.

High field irreversibility in NiFe_2O_4 nanoparticles (abstract)

R. H. Kodama and A. E. Berkowitz

Physics Department, University of California, San Diego, La Jolla, California 92093 and Center for Magnetic Recording Research, University of California at San Diego, La Jolla, California 92093

E. J. McNiff, Jr. and S. Foner

Francis Bitter National Magnet Laboratory, MIT, Cambridge, Massachusetts 02139

Several anomalous magnetic properties of organic coated NiFe_2O_4 nanoparticles have been reported previously by Berkowitz *et al.*¹ These properties included low magnetization with a large differential susceptibility at high fields, shifted hysteresis loops after field cooling below 50 K, and Mössbauer spectra indicating a fraction of the material being magnetically ordered but not responsive to applied fields. It was suggested that a "strongly anisotropic phase" was present on the particles surface, and that the organic coating was responsible for producing high local anisotropy fields on the surface atoms. The present study extends the original work in several ways. We find that the lack of saturation in high fields is accompanied by irreversibility up to 20 T, in some cases. We have confirmed the previously reported behavior, in addition to observing similar behavior in samples prepared without the organic surfactant. This implies that we are observing a finite size effect. We have recently reported time dependence of the remanent magnetization which persists down to 0.4 K and does not appear to follow a thermally activated law. Instead, the viscosity becomes temperature independent below 2 K.² The model we propose for the high field irreversibility as well as the previously reported behaviors, is that there is a layer of spins at the surface which are spin glass-like, and that these spins can be reoriented irreversibly by a field or by thermal activation. The effect of surface spin interactions on magnetization relaxation will be discussed. © 1996 American Institute of Physics. [S0021-8979(96)63008-1]

Sputter deposited Co/CoO composite materials

J. Y. Yi, C. L. Platt, M. L. Rudee, A. E. Berkowitz, and T. L. Cheeks
University of California, San Diego, California 92039

Magnetic composites consisting of ultrafine particles of Co and CoO were prepared by dc reactive magnetron sputtering in a Ar+O₂ gas mixture. The films were composed of 60–140 Å particles of hcp Co and fcc CoO. The magnetization, coercivity, and particle size were found to be dependent on the O₂ partial pressure, such that the magnetization decreased and the coercivity increased to a maximum value of 1000 Oe with increasing O₂ partial pressure. A shift in the hysteresis loop was observed for several samples, indicating exchange coupling between the Co and CoO. © 1996 American Institute of Physics. [S0021-8979(96)04608-X]

I. INTRODUCTION

Recently, composite thin films consisting of two insoluble metals or a metal embedded within an insulator have been the subject of an intense study due to their potential applications in magnetic and magneto-optic recording as well as other applications.^{1–3} Metal-metal composites such as Co-Ag, Co-Cu, and metal-oxide composites such as Fe-SiO₂, Co-Al₂O₃ and Co-CoO are of interest because of their GMR effects, large coercivities, and exchange anisotropy.^{4–6} Particularly interesting are thin-film metal-oxide composites in which the metal, a ferromagnet, is embedded within an antiferromagnetic oxide. These materials are known to exhibit exchange anisotropy such that the hysteresis loop shifts when the specimen is cooled down in a strong magnetic field. It is well known that the unidirectional exchange anisotropy exists in the bulk Co/CoO system.⁷

Thin films of Co/CoO have shown excellent properties such as high coercivity, perpendicular anisotropy, enhanced Kerr rotation, and exchange anisotropy.^{8,9} The films typically consisted of fine particles of hcp Co and fcc CoO. The Neel temperature of CoO is about 293 K. Thin films of the composite material have been prepared using two different techniques, namely, rf reactive sputtering of Co in a Ar+O₂ gas mixture and reactive electron beam evaporation in which Co was evaporated in an O₂ environment.^{10,11} In general, the microstructure of the films consisted of columnar grains with chains of fine Co particles surrounded by CoO particles. The magnetic properties, such as the saturation magnetization and the coercivity were found to be dependent on the O₂ partial pressure. Loop shifts of 1.6 kOe due to the exchange anisotropy were observed in 9000 Å sputter deposited films cooled to 120 K.¹⁰

In this study, we have prepared Co/CoO composite materials using dc reactive magnetron sputtering with a single Co target in a Ar+O₂ gas mixture. We discuss the influence of oxygen partial pressure on the microstructure and magnetic properties of these films.

II. EXPERIMENTAL DETAILS

Thin films of Co/CoO were prepared by dc reactive magnetron sputtering using a Ar+O₂ gas mixture. Prior to deposition the base pressure was better than 10⁻⁷ Torr and the total pressure during deposition did not exceed 2 mTorr. During deposition the Ar gas flow rate was fixed at 5 sccm and the O₂ flow rate was systematically adjusted to obtain

the desired Co/CoO composition. The typical deposition conditions were a dc power of 20 W and a total pressure of 1.6 mTorr. A preliminary series of thin films were deposited to determine the deposition parameters, i.e., power, pressure, and Ar+O₂ mixture that resulted in Co/CoO thin films. The parameters were chosen to obtain the Co and CoO rather than Co₂O₃ or Co₃O₄ phases.

The films (5000 Å) were deposited onto glass substrates at a deposition rate of about 200 Å/min. The substrates prior to deposition were at room temperature, however, during deposition a slight increase in temperature of about 30 °C was observed. Presputtering of the Co target was performed using Ar followed by presputtering in the Ar+O₂ gas mixture used during film deposition.

The composition and microstructure of the films were investigated using x-ray diffraction (XRD) and transmission electron microscopy (TEM). The magnetic properties were measured using a vibrating sample magnetometer (VSM) and a SQUID magnetometer.

III. RESULTS AND DISCUSSION

Figure 1 shows the x-ray diffraction analysis (Co K α , $\lambda=1.7902$ Å, 1.8 kW) for 5000-Å-thick films deposited on glass substrates using Ar plus increasing partial pressure of O₂. The spectra show that the films deposited using pure Ar were hcp Co as indicated by the x-ray diffraction peaks of the (002), (101), and (100) planes. With increasing O₂ partial pressure the amplitude of the Co peaks decrease and the (111), (200) peaks of CoO gradually increase. Above a critical O₂ partial pressure (0.082 mTorr), the (111) peaks of Co₃O₄ begin to appear. The x-ray diffraction results show that Co/CoO films can be controllably obtained between 0.062 and 0.074 mTorr O₂ partial pressure. Beyond this partial pressure window, the films consist of mostly CoO or the Co₃O₄ phase.

A suggested mechanism for cobalt oxide formation has been described by Hecq *et al.*¹² Hecq suggests that when the oxygen partial pressure P_{O_2} is below a certain critical value P^* ($P_{O_2} < P^*$), the atoms sputtered from the target are metallic Co. The atoms are subsequently partially oxidized on the substrate resulting in a film composed of Co and CoO. When the oxygen partial pressure is between the critical value and 10% of the total pressure ($P^* < P_{O_2} < 10\%$ of the total pressure), the target surface oxidizes gradually and the

FIG. 1. X-ray diffraction spectra of Co/CoO thin films deposited using WDC, Ar+ increasing O_2 partial pressure.

sputtered atoms are CoO rather than Co. The additional oxidation at the substrate surface results in both CoO and Co_3O_4 films. When $P_{O_2} > 10\%$ of the total pressure, the deposited film is entirely Co_3O_4 because the target surface is fully oxidized. Thus, the overall composition of the deposited films is expected to be dependent on oxygen partial pressure.

The x-ray results reported here confirm that the film composition is dependent on both the O_2 partial pressure and the input power. Since the O_2 partial pressure probably influences the oxidation rate of the target and the substrate, it is expected that at a given input power the oxide formation increases with increasing O_2 partial pressure. When the O_2 partial pressure exceeds a certain value, Co_3O_4 is expected to form. The input power should influence the sputter rate of the target material such that at a constant O_2 partial pressure and increasing input power, the target sputter rate will exceed the oxidation rate. This should result in formation of less CoO and more Co.

Transmission electron microscopy was performed on a series of samples deposited at 20 W and an O_2 partial pressure ranging from 0.050 to 0.074 mTorr. For the samples deposited at 0.050 and 0.070 mTorr, the microstructure consisted of fine equiaxed grains of Co and CoO that appear to extend throughout the film thickness. The electron diffraction patterns were consistent with the x-ray diffraction measurements confirming the formation of hcp Co and fcc CoO.

Figures 2(a)–2(c) show the bright-field TEM images obtained from 400-Å-thick films deposited at 0.050, 0.070, and 0.074 mTorr, respectively. The particle size was estimated from both bright-field and dark-field images. The particles size for samples deposited at 0.050 mTorr O_2 partial pressures were about 60 Å, while the particle size for the samples deposited at the higher O_2 partial pressures were about 140 Å. Also, the samples deposited at 0.050 mTorr appeared to

FIG. 2. Bright-field electron micrographs of Co/CoO films deposited at 20 W and O_2 partial pressure of (a) $P_{O_2} = 0.05$ mTorr, (b) $P_{O_2} = 0.07$ mTorr, and (c) $P_{O_2} = 0.074$ mTorr. The scale bar represents 100 nm.

have amorphous regions between the crystalline particles while those deposited at 0.074 mTorr were fully crystalline. It should be noted that the fine equiaxed Co/CoO grains reported here differ significantly from previous reports of larger columnar microstructures with mutually parallel chains of fine Co and CoO particles. The reason for the differences in microstructure may be related to the deposition conditions and is currently under investigation.

The coercivity (H_C) and saturated magnetization (M_s) measured parallel to the film plane as a function of increasing O_2 partial pressure are shown in Fig. 3. The saturated magnetization of pure Co films measured 1400 emu/cm³ a value comparable to the bulk Co value of 1420 emu/cm³. Figure 3 shows that the M_s remained fairly constant at low values of O_2 partial pressure. As the partial pressure increases above 0.050 mTorr a more dramatic decrease in the M_s is observed. The decrease in magnetization with increasing O_2 partial pressure is most likely due to the increasing

FIG. 3. Saturation magnetization and coercivity of Co/CoO films at room temperature as a function of O_2 partial pressure.

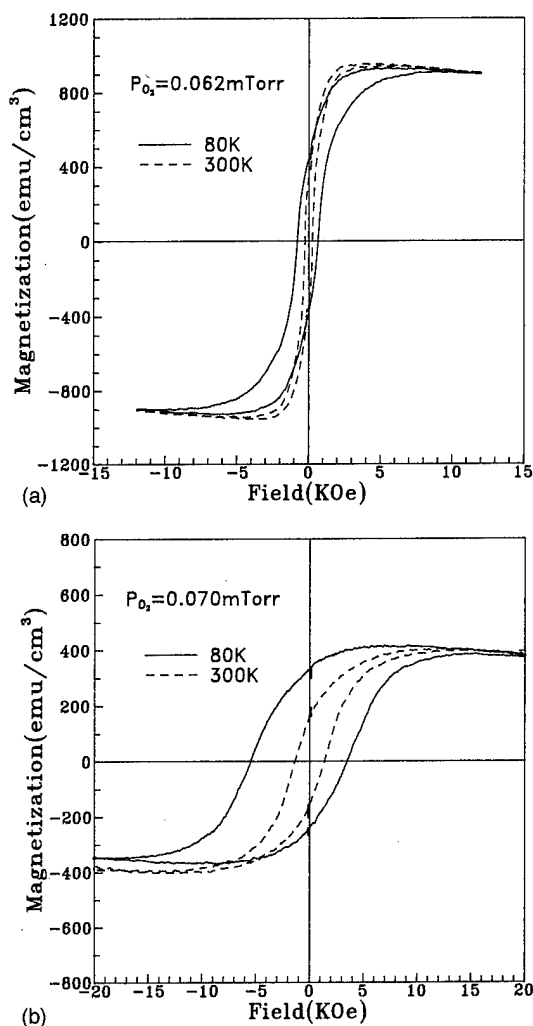

FIG. 4. Magnetic hysteresis loops of Co/CoO films at 80 K. (a) O_2 partial pressure of 0.062 mTorr and (b) O_2 partial pressure of 0.070 mTorr. Solid loops were measured after cool down to 80 K in a strong field.

amount of antiferromagnetic CoO within the film as confirmed by x-ray measurements. Above 0.078 mTorr, the M_s approaches zero, which corresponds to the Co_3O_4 phase transformation.

The H_c of the deposited films (Fig. 3) shows an initial increase to about 150 Oe with increasing O_2 partial pressure from 0.010 to 0.060 mTorr. As the O_2 partial pressure increases from 0.060 to 0.070 mTorr, the H_c increased substantially to a maximum value of 1000 Oe. Further increase in the O_2 partial pressure results in a slight reduction in H_c to about 650 Oe. The maximum H_c value obtained here is similar to the values obtained from previous work. The main difference is that the measurements were obtained from the magnetization parallel to the film plane rather than perpendicular to the film plane.¹⁰

A distinguishing property of Co/CoO composite films is its exchange anisotropy. The hysteresis loop shifts were measured parallel to the film plane after the specimen was cooled down to 80 K in a 20 kOe field. Figure 4 shows the magnetic hysteresis loops for two Co/CoO thin films deposited at two different partial pressure of O_2 . The figure shows that the films deposited at the higher oxygen partial pressure, i.e., CoO rich, had a larger loop shift than the films deposited at the lower oxygen partial pressure. The loop shift value for a higher O_2 partial pressure was 1000 Oe while the value for the lower O_2 partial pressure was 85 Oe. These results show that the exchange anisotropy exists in these films and that it is very sensitive to the O_2 partial pressure, i.e., the Co to CoO ratio. The exchange field or loop shift is comparable to previously reported values, however, it is difficult to compare the Co to CoO ratio for a direct comparison. Further studies to determine the extent of the exchange anisotropy as a function of O_2 partial pressure, Co to CoO, ratio and particle size/volume fraction are currently underway.

IV. SUMMARY

We have successfully fabricated Co/CoO composite thin films using dc reactive magnetron sputtering in a $Ar+O_2$ gas mixture. The films exhibit a fine grained equiaxed microstructure that appear to extend throughout the film thickness. The particle sizes ranged from 60 to 140 Å and were found to be dependent on the O_2 partial pressure. Both the magnetization and coercivity are dependent on the O_2 partial pressure and a maximum coercivity value of 1000 Oe is measured. In addition to controlling the Co/CoO ratio over a fairly wide range of O_2 partial pressures, exchange anisotropy is observed in the films. This suggests that a strong interaction between of Co and CoO exists within these sputter deposited thin films.

The magnetization process in an array of $2\ \mu\text{m} \times 2\ \mu\text{m} \times 0.04\ \mu\text{m}$ permalloy particles fabricated on a 100 nm carbon membrane was investigated by means of high-resolution Lorentz microscopy and electron holography in magnetic fields parallel and perpendicular to the film surface. For perpendicular fields, the magnetization reversal was found to begin with the nucleation of a vortex which gradually transformed into a closure domain configuration. At the remanent state, the flux closure was achieved with the generation of a new type of doubled domain wall. © 1996 American Institute of Physics. [S0021-8979(96)01708-0]

I. INTRODUCTION

Recent progress in microfabrication techniques now enables us to produce a variety of magnetic microstructures. An array of micron-size permalloy particles, for example, may be used as a device for applying in submicron scale spatially modulated magnetic fields on an underlying layer. According to the domain observation of submicron rectangular permalloy particles by Heffernan *et al.*,¹ the magnetic state of such particles can be easily controlled by a small external magnetic field less than 5 mT and their domain structures are extremely reproducible. We have tested this idea by fabricating a permalloy square particle array on a two-dimensional superconducting niobium film.^{2,3} The superconducting properties of the underlying niobium film were significantly influenced by the modulated local fields created by the array, revealing peculiar behaviors such as quantum oscillations in the magnetoresistance and flux guide effects which stabilize the superconducting state.^{3,4} Although qualitative explanations of the origin of these behaviors were given in previous studies,³⁻⁵ there are still unsolved problems associated with the magnetic state of the particles. Properties of magnetic domain walls and their movements in the particles are therefore a key to fully clarify the origin of these phenomena.

In this study, our aim is to directly observe the domain structures inside the micron-size particles and the flux distribution outside the particles under magnetic fields parallel and perpendicular to the sample surface by means of high-resolution Lorentz microscopy and electron holography.

II. EXPERIMENTAL PROCEDURE

The magnetic particle array was fabricated by electron beam lithography and conventional sputtering techniques on top of a 30 nm carbon membrane. The array consists of 2×10^5 permalloy $\text{Fe}_{20}\text{Ni}_{80}$ square particles with an edge length of $2\ \mu\text{m}$ and a thickness of 40 nm, sandwiched by Mo protecting and buffer layers of 10 nm. The total thickness of the sample is only 90 nm so that the sample is transparent for an electron beam. The structure of the array is a square lat-

tice with the lattice constant of $4\ \mu\text{m}$, which gives the maximum dipole field of 0.3 mT in the homogeneously magnetized state. The particles are thus considered as more or less isolated. The magnetocrystalline anisotropy is negligible for $\text{Fe}_{20}\text{Ni}_{80}$, and the in-plane easy axes are mainly determined by the shape anisotropy of the particles. The estimated in-plane anisotropy field is 0.9 T.

The Lorentz micrographs reveal the domain walls as dark or light lines due to the divergence or overlap of the electron beams after passing magnetic domains with different magnetization directions. On the other hand, the electron holograms contain the amplitude and phase of the electron beam transmitted through the sample. The optically reconstructed image interfered with a planar comparison wave reveals contour fringes of constant phase, that is, the flux distribution.

A 300 kV field emission microscope (Hitachi Co. Ltd.) was used for the observation at 4.2 K in parallel fields. For the observation in perpendicular fields, a 200 kV microscope (Hitachi Co. Ltd.) was operated only at room temperature. Perpendicular fields up to 1.6 T were applied by adjusting the current supplied to the objective lens. Obtained images were recorded on either video tapes or films.

III. RESULTS AND DISCUSSION

Initial studies were made in parallel fields at 4.2 K using the defocused mode of Lorentz microscopy. A field profile of typical domain structures observed in permalloy particles together with inferred domain structures are shown in Fig. 1. The parallel field $\mu_0 H_{\parallel}$ was applied along a direction tilted by $\sim 30^\circ$ from the vertical axis as indicated in the figure. When $\mu_0 H_{\parallel}$ is zero, flux closure was achieved within the particles by four-closure domain (left particle) or seven-closure domain (right particle) configuration segmented by 90° and 180° domain walls. Bright and dark domain walls were observed according to the circulation of the magnetization in either clockwise or anticlockwise direction, respectively. Some of the particles exhibited distorted seven-

FIG. 1. Parallel field profile of four-closure domain and seven-closure domain configurations observed by means of Lorentz microscopy together with the inferred domain structures.

closure domain configurations, in which one of the circulation dominated. This may be due to the domain wall pinning by irregularities found along the edges of the particles.

As $\mu_0 H_{\parallel}$ is increased, domains with magnetization directions close to the external field direction grow. This results in a shift of the intersection of the 90° domain walls in the four-closure domain configuration toward the corner of the particle (left column in Fig. 1). The initial movement of the intersection agrees well with the trajectory calculated by minimizing the free energy composed of the magnetic energy, the magnetostatic energy, and the domain wall energy.⁶ The intersection first moves perpendicular to the applied field direction and gradually approaches the corner of the particle. When the parallel field is increased above 7 mT, the intersection splits into two with the generation of 180° domain wall. Further increase of the field sweeps this wall towards the right side of the particle, leading to a rather simple nonsolenoidal domain structure with two 90° walls.

In the case of the seven-closure domain configuration (right column in Fig. 1), with an increase of $\mu_0 H_{\parallel}$, two triangular segments with the magnetization direction along the external field grow until the vertices reach the edges of the particle accompanied by the annihilation of 180° domain walls. Above 8 mT, the central domain is gradually squashed by the growing triangular segments, resulting in a nonsolenoidal structure as observed in the four-closure domain structure. In the demagnetizing process, some of the seven-closure domain configurations are found to transform abruptly to four-closure domain configurations within a transition time of less than 100 ms. This suggests that the four-closure domain configuration is energetically favorable relative to the seven-closure domain configuration.

FIG. 2. Lorentz micrograph and flux line maps taken under a field of 0.16 T applied perpendicular to the particle surface.

Measurements in perpendicular fields $\mu_0 H_{\perp}$ were performed at room temperature by means of Lorentz microscopy and electron holography. Prior to the measurements, the sample was magnetized perpendicular to the film plane in a magnetic field of 1.2 T and the images were captured while the applied field was decreased from 1.2 T to zero. When the field is in the range of $1.2 \text{ T} \geq \mu_0 H_{\perp} \geq 0.6 \text{ T}$, the particles are uniformly magnetized perpendicular to the film plane. Interestingly, dark or bright dots began to appear in the particles at $\mu_0 H_{\perp} = 0.4 \text{ T}$, reflecting the vortex formation associated with the nucleation of magnetization reversal. This can clearly be seen in Fig. 2 which shows a Lorentz micrograph of two particles soon after the nucleation together with flux line maps taken by electron holography. The bright and dark dots correspond to the vortices with anticlockwise and clockwise circulation, respectively. The intensity analysis of the central part of the vortex in the Lorentz micrograph based on Fuller and Hale's method⁷ shows that the intensity distribution reflects an exponential decay of the perpendicular magnetization component which is characteristic of the vortex.⁸ This fitting yields the exchange length of 5 nm. The magnetization at the center of the vortex therefore directs opposite to the external field direction, gradually changes its direction into the film plane within the exchange length and then toward the external field direction. The flux line map also supports the above mentioned feature of the vortex. The density of the fringes, that is, the in-plane magnetization intensity is lower at the edges of the particles than in the vicinity of the vortex center.

In most cases, the vortices are located at the corner of the particles. This can be understood from the fact that the strongest demagnetizing field is exerted on the edge of the particle for a perpendicularly magnetized thin plate. At the initial stage of the reversal, the magnetization tends to rotate into the film plane because of the large demagnetizing field

FIG. 3. Perpendicular field profile of the development of the vortices observed by means of Lorentz microscopy.

and then forms a vortex to avoid the volume and surface charges. The initial size and location of the vortex may be closely related with the shape of the rounded corner as is expected from the van den Berg's approach.⁹ In addition, the presence of the flux lines between the particles clearly shows that there is a dipole interaction although it is difficult to quantify its strength. This is also an important factor that determines the location of the vortices.

Figure 3 shows a field profile of the vortices taken by Lorentz microscopy. The vortices, initially nucleated at the corner of the particle, steadily move toward the center with decreasing $\mu_0 H_{\perp}$ to 0.10 T. In the figure, there is observed a small sign of the pinned domain walls which seem to restrict the movement of the vortices. When $\mu_0 H_{\perp}$ reaches 0.06 T, a significant difference is observed in the domain configuration between the top and bottom particles. The vortex in the top particle stays in the vicinity of the corner whereas the vortex in the bottom particle stays near the center of the particle. This difference results in a seven-closure domain configuration for the top particle and a four-closure domain configuration for the bottom particle in the remanent state. Figure 4 shows a Lorentz micrograph, corresponding flux line maps and inferred magnetization distributions for the four-closure domain and the seven-closure domain configurations. In the case of the four-closure domain configuration, complete flux closure seems to be achieved. Since the period of the fringes is equivalent to one flux quantum ($\phi_0 = 4.14 \times 10^{-15}$ Wb), the in-plane magnetization is evaluated as 0.83 T from the relation $n\phi_0/S$, where $n(=8)$ is the number of the fringes and $S(=4 \times 10^{-14} \text{ m}^2)$ is the cross-sectional area which the circulating magnetization passes through. The obtained value coincides well with the saturation magnetization of bulk permalloy, and this proves that the magnetization lies in plane. More interesting is the seven-closure domain configuration. One should notice that there is a double wall in between the

FIG. 4. (a) Lorentz micrograph, corresponding (b) flux line map, and (c) the inferred magnetization distribution of the four-closure domain and the seven-closure domain configurations in the remanent state.

triangular segments in the Lorentz micrograph. In the corresponding flux line map, the in-plane flux density of the upper left and the lower right part of the particle is less, suggesting that the magnetization stands out of the film plane. As shown in the schematic domain structure, the double wall consists of a kind of combined 90° domain walls, in which the magnetization changes its direction at the expense of magnetostatic energy due to the surface charge. It should also be noted that the remainders of the vortices can be recognized in the flux line map. The reason of the appearance of the seven-closure domain type configuration may be related to the creation of the vortex with counter circulation.

The spontaneous nuclear spin ordering in the simple diamagnetic metals Cu and Ag has been studied by neutron diffraction using the spin dependent part of the nuclear cross section. Simple antiferromagnetic ordering of type I has been found in zero field for these fcc-systems below 60 and 560 pK for Cu and Ag, respectively. The ordering in an applied field has been investigated and the phase diagrams have been determined: a very complex phase diagram with different magnetic structures, strong hysteresis, and time dependence was found for Cu, while in Ag the phase diagram is very simple. Comparison with *ab initio* calculations allows a rather deep insight into the interactions leading to the ordering. © 1996 American Institute of Physics.

[S0021-8979(96)39108-8]

I. INTRODUCTION

The weakest interaction in solids is between nuclear spins: it can be smaller than the interaction between electronic moments by 10 to 15 orders of magnitude! To study these interactions is therefore a very interesting and challenging problem for theory and experiment. For such studies, the determination of the ordered ground state is the crucial experiment. The only way to achieve this is by neutron diffraction. But, due to the smallness of the nuclear moments, the magnetic cross section of the neutrons cannot be used. Fortunately, the nuclear cross section has a spin dependent part, which can be used to study the ordered nuclear ground state. Suitable systems have to be chosen bearing in mind, that the smallness of the interaction results in an extremely low transition temperature and that any electronic magnetism will overrule any tendency of the nuclear spin system to order spontaneously. Thus, only such systems are of interest, of which one knows, that they can be cooled to extremely low temperatures and that they are ideal electronic diamagnets. The simple metals Cu and Ag fulfill these requirements ideally. Systematic investigations by nuclear magnetic resonance (NMR) and susceptibility measurements on Cu and Ag have given strong evidence, that there is spontaneous nuclear ordering below 60 nK and 560 pK, respectively.¹ From such measurements, it was concluded that the ordering should be antiferromagnetic, but no firm proof could be given by these techniques.

In the temperature range of interest particular phenomena and properties of a solid become key issues: it is most likely that the interactions are simple and tractable by *ab initio* calculations [dipolar and Rudermann, Kittel, Kasuya, Yosida (RKKY) interactions]; the nuclear system is

“completely” decoupled from the surrounding electronic and lattice system, talking between these systems occurs through the very slow spin lattice relaxation only with typical time constants of hours. No temperature measurement in the usual sense is possible in this situation. Since cooling is by adiabatic demagnetization, ordering takes place at constant entropy S . In this situation phenomena can be studied, which are very difficult or impossible to study in electronic magnets: A prominent example is the antiferromagnet on the fcc-lattice, where the topological frustration competes with antiferromagnetism, in which situation electronic magnets tend to change the structure at the ordering temperature to break the frustration. A further advantage of the extraordinary low energy scale of nuclear magnets is the corresponding long time scales for onset of order or changes of order. In conclusion, many phenomena not accessible experimentally in electronic magnets are at the experimentalist's hands in nuclear magnets.

In this paper, the results of our intense studies of Cu and Ag by neutron diffraction will be presented. Not only will it be shown, that neutron experiments are feasible at extremely low temperatures, but that new and exciting phenomena of general interest were found, too, as a reward for the efforts necessary to perform such experiments.

II. EXPERIMENT

It is appropriate to shortly discuss some properties of the neutron cross section used in the experiments to be discussed, for more details see Ref. 2. The nuclear polarization $\langle P_N \rangle$ enters the structure factor as $\langle P_N \rangle (b^+ - b^-)$, in analogy to the electronic magnetic scattering length, $(b^+ - b^-)$ being the spin dependent part of the nuclear scattering

FIG. 1. Scan along $[1\eta\eta]$ at $T \leq 60$ nK in Cu. The width of the observed peak at $\eta=1/3$ is determined by the resolution.

length. However, since the scattering is due to nuclear forces, there is no interaction vector or $\sin \alpha$ -term as in electronic magnetism. Therefore, the determination of the moment direction in nuclear magnets can not be performed by a systematic measurement of different Bragg-reflections as in electronic magnets, but needs experiments with polarized neutrons and polarization analysis. As $b, (b^+ - b^-)$ does not show any Q dependence, an obvious way to separate nuclear from electronic magnetic scattering. $(b^+ - b^-)$ is comparable in size to b for many isotopes. Otherwise, the procedure for the magnetic structure determination is the same for the nuclear magnets as for electronic magnets. It is worth mentioning that not only the scattering, but the absorption may depend on $\langle P_N \rangle$, giving yet another way to measure $\langle P_N \rangle$ by neutrons.

Obviously the biggest hurdle to be passed in such studies is to reach the necessary low temperatures. It is generally true, that there is no technique to achieve continuous cooling in the sub-mK range. All further cooling has to be done by adiabatic demagnetization.³ For the studies of Cu and Ag, a two stage adiabatic demagnetization procedure was used: the first stage is a large polycrystalline piece of copper, which is demagnetized into the μ K range, the electronic and the lattice system being in thermal equilibrium with the nuclear system. This powerful stage cools the second stage, the actual sample (Cu or Ag-single crystal), to the corresponding temperature. From there this stage and only the nuclear system of it is demagnetized to zero field, hopefully ending up in the ordered regime of the nuclear system. It is clear, that at the end of such a cooling cycle the nuclear system, now completely decoupled from its lattice and electronic system, will warm up according to the external heat leak into it. Therefore, the heat leak must be minimized to a point where the neutron beam determines the heat load. In Cu the time for experiments in the ordered phase was about 6 min, while in Ag more than 30 min were achieved. This difference is

FIG. 2. The magnetic phase diagram of the nuclear spin ordering in Cu. The corresponding structures are indicated. Note the very strong coexistence of the different phases especially at low fields. The numbers given in the diagram are intensities in arbitrary units.

due to the different spin-lattice relaxation times. The time needed to prepare the system for these short periods, i.e., for the cooling procedures was between one and two days.

III. RESULTS

A. Copper

The neutron diffraction experiments have been performed at the DR3-reactor of Risø National Laboratory using a two axis diffractometer. Guided by theoretical predictions⁴ a $(1,0,0)$ reflection was found in zero field below $T_N=60$ nK demonstrating, that the ordering of the nuclear spin system is of type I for this fcc system. Its width was resolution limited. When applying an external magnetic field the $(1,0,0)$ -peak disappeared around 0.08 mT and reappeared at 0.12 mT until at 0.25 mT the field had completely destroyed the antiferromagnetic ordering. Again guided by theory, scans along the $[1,\eta,\eta]$ direction have been performed at intermediate fields, yielding a peak at $\eta=1/3$ as shown in Fig. 1. From such measurements, a complete phase diagram has been mapped out as shown in Fig. 2.⁵ It must be noted that the $(1, 1/3, 1/3)$ type of structure has never been observed for such fcc anti-ferromagnets before.

A striking feature of this phase diagram is the strong coexistence of the different phases along the phase boundaries. A very strong time and history dependence accompanied every passage through the phase diagram.⁶ As there was no way to determine the thermodynamic parameters, entropy S or T , mainly because of the strong hysteresis in the phase diagram, the temperature coordinate had to be replaced by a time coordinate where $t=0$ represents the end of the demagnetization. Measurements with the field direction along different crystallographic direction have lead to another phase diagram shown in Fig. 3. It is obvious that with field along $[1,0,0]$ and $[0,1,1]$ there are the three phases as in Fig. 2, but that for field along $[1,1,1]$ the high field $(1,0,0)$ phase is missing. Whether there is no ordering in this situation or whether there is another, not yet discovered type of ordering is not clear.⁷

FIG. 3. The magnetic phase diagram of Cu for a field along different directions. Note the missing high field phase around [111].

B. Silver

Again guided by theory, in zero field below $T_N=560$ pK (Ref. 8), the same structure was found as in Cu, namely type I for the fcc lattice. When applying a magnetic field no new phase was observed, yielding the simple phase diagram shown in Fig. 4. This phase diagram resembles very closely the phase diagram of an extremely weakly anisotropic antiferromagnet, yet no additional phase boundary has been detected. No hysteresis nor any time or history dependencies have been observed. However, a very selective occurrence of the three degenerate domains of the (1,0,0) structure has been observed: for example, demagnetization along [0,0,1] resulted in the occurrence of the (0,0,1) domain only and no particular time dependence was observed. Thus, this is definitely a single- k structure. No evidence for the predicted multi- k structure in finite fields has been obtained. In these investigations the entropy S could be determined at each measurement and thus the phase diagram of Fig. 4 is presented as H, S diagram. This was achieved by using the spin dependent part of the absorption, which without any calibration yields the direct nuclear polarization, from which S can be deduced. By this technique, it was found that at finite fields inside the ordered phase a significant direct polarization of the nuclei coexists with the antiferromagnetic polarization. The corresponding susceptibility $\langle P_N \rangle / H$ was found to be 0.36 and independent of S .

IV. CONCLUSION

The neutron scattering studies on the simple metals Cu and Ag have uniquely proven the existence of a long range antiferromagnetic ground state of the respective nuclear spin systems. A new antiferromagnetic structure for fcc systems was found at 0.1 mT in Cu. The determination of the magnetic unit cells is only a part of a complete magnetic structure determination: the direction of the magnetic moments with respect to the crystallographic axis remains to be deter-

FIG. 4. The H, S phase diagram of the nuclear spin system in Ag for two field directions. The lines are guides for the eye. The phase transition appears to be continuous all along the phase boundaries.

mined. The phase diagrams are surprisingly different, perhaps an indication of the influence of the size of the spin: Cu has $I=3/2$, while in Ag $I=1/2$, which makes Cu a classical and Ag a quantum system. The assumed and calculated structures seem to agree with experiment; in Cu in particular, the agreement covers the whole phase diagram, while in Ag at present agreement is limited to zero field. Again this might be a consequence of $I=1/2$. In both cases, dipol-dipol and RKKY interaction suffice to describe the structures found. Although *ab initio* calculations are feasible, the identification of the true ground state is difficult due to the high degree of degeneracy in these topologically frustrated fcc antiferromagnets. The remarkable stability of the one domain created during demagnetization in Ag should be noted as well. In Cu various time dependent phenomena have been observed. Whether they are due to the restriction $S=\text{const}$ during ordering or whether they reflect the slow ordering remains to be clarified by further investigations. In any case, it has become clear that nuclear magnets are not just another class of magnets, but represent systems whose properties add new interesting and fundamentally important phenomena to our knowledge of magnetic ordering. This outcome balances the enormous efforts necessary to perform such experiments successfully.

Critical properties of the spin Peierls transition in CuGeO_3

M. D. Lumsden, B. D. Gaulin, and H. Dabkowska

Department of Physics and Astronomy, McMaster University, 1280 Main St. West, Hamilton, Ontario L8S 4M1, Canada

The spin-Peierls transition in CuGeO_3 has been studied using x-ray diffraction techniques. The order parameter of the $(1/2, 5/2)$ superlattice reflection has been measured with a temperature stability of ± 5 mK. Careful analysis has been performed fitting the order parameter to both an ordinary power law in the reduced temperature as well as to a power law with the first correction to scaling term included in an attempt to determine a consistent value of the critical exponent β . We obtain a value of β of 0.36 ± 0.03 at a transition temperature of 14.06 ± 0.02 K. This value of β is consistent with conventional three-dimensional Heisenberg or XY behavior and clearly inconsistent with the tricritical values reported previously. © 1996 American Institute of Physics. [S0021-8979(96)39208-4]

INTRODUCTION

The spin-Peierls transition occurs in one-dimensional $S=1/2$ Heisenberg spin chains in which the spins couple to the phonons of the lattice. Below some transition temperature, the lattice undergoes a structural dimerization which is driven by magnetic interactions within the chain. The magnetic susceptibility falls isotropically to zero due to the presence of a magnetic energy gap separating the nonmagnetic singlet ground state from the triplet excited states. This transition had previously only been found in a few organic compounds until the discovery, by Hase *et al.*,¹ of such a transition in the inorganic insulator CuGeO_3 . Hase *et al.*¹ observed the characteristic magnetic susceptibility drop below a temperature of 14 K. Since this time, many other characteristic properties of the spin-Peierls transition have been found in this material. For instance, the magnetic energy gap has been observed using neutron scattering² and the singlet to triplet nature of the excitations have been demonstrated by such measurements in the presence of a magnetic field.³ In addition, the characteristic dimerization of the chains has been observed using x-ray and neutron diffraction.⁴

One question which remains unclear is what the true value for the critical exponent β describing the order parameter is for the transition in this material. Neutron scattering results seem to yield an exponent consistent with tricritical behavior⁵ while thermal expansion measurements yield a value consistent with conventional three-dimensional (3D) behavior.⁶ This uncertainty motivated us to carefully measure the order parameter using x-ray scattering techniques.

EXPERIMENTAL DETAILS

The lattice parameters of CuGeO_3 at room temperature are $a=4.81$ Å, $b=8.47$ Å, and $c=2.941$ Å and the linear chains consist of $S=1/2$, Cu^{2+} ions stacked along the c axis. Below a temperature of 14 K, there is a dimerization along this chain which is accompanied by slight displacements of the $O(2)$ atoms⁷ yielding a doubling of the unit cell along the a axis. Consequently, we find superlattice reflections with indices $(h/2, k, l/2)$ with h and l odd and k odd or even. This has been observed in electron diffraction,⁸ x-ray and neutron scattering⁴ and later neutron diffraction⁷ studies. We have chosen to measure the order parameter of the $(1/2, 5/2)$ su-

perlattice reflection due to its relative strength and to allow for a direct comparison with other studies where the identical reflection was measured.

A single crystal of CuGeO_3 was grown from self flux by the slow cooling method with approximate dimensions $2 \times 1 \times 0.5$ mm³. The sample was mounted in a Be can in the presence of a He exchange gas. This can was then connected to the cold finger of a closed cycle He refrigerator. Within the temperature range of interest, a temperature stability of ± 5 mK was obtained. Cu $K\alpha$ radiation from an 18 kW rotating anode x-ray generator, further monochromatized via the $(0,0,2)$ reflection of a focusing pyrolytic graphite (PG) crystal, was used as the incident radiation in these measurements. No analyzer crystal was employed.

RESULTS AND ANALYSIS

The data obtained for the peak intensity as a function of temperature at the $(1/2, 5/2)$ superlattice reflection is shown in Fig. 1. The peak intensity at the ordering wave vector is proportional to the square of the order parameter. Prior to performing the measurements, the effect of changes in lattice parameters,^{5,7} was carefully investigated. Both transverse and longitudinal scans were performed at several temperatures, some near T_{sp} and some far below T_{sp} . With our relatively low resolution configuration, no change in peak position, or line shape, could be detected. Thus, the measurements were performed by varying the temperature in 5 mK increments and monitoring the intensity at $(\frac{1}{2}, 5, \frac{1}{2})$.

Despite an extensive search, no critical scattering was observed above T_{sp} . However, the best fit to the data, represented by the solid line in Fig. 1 is systematically lower than the data in the immediate vicinity of T_{sp} . This may suggest the presence of weak critical scattering very close to the transition temperature.

The critical behavior of the order parameter has been determined by fitting the intensity to an ordinary power law in the reduced temperature:

$$\text{Intensity} = I_0 t^{2\beta} + \text{Background}, \quad (1)$$

where the reduced temperature t is $(T_{sp} - T)/T_{sp}$. This expression is expected to be valid in the asymptotic region where $T \rightarrow T_{sp}$. In addition to this, another form of the same equation was used

FIG. 1. X-ray scattering peak intensity as a function of temperature at the $(1/2, 5/2)$ ordering wave vector. The solid line represents the best fit to a power law with correction-to-scaling included. The insert shows the same data on a logarithmic scale (a and b are displaced vertically). The solid line (b) represents the same fit with correction-to-scaling included while the solid line (a) represents a fit to a straight power law with the same value of β .

$$\text{Intensity} = I_0 t^{2\beta} (1 + A t^\Delta) + \text{Background}, \quad (2)$$

where Δ is approximately 0.5.⁹ This form includes the first *correction-to-scaling confluent singularity* term, which is the first-order correction for deviations of the data from the asymptotic region. The fits were performed using data in the region $0.004 < t < 0.11$.

The fit shown in Fig. 1 represents the best fit to Eq. (2) yielding a value of $\beta = 0.36 \pm 0.03$ at a transition temperature of 14.06 ± 0.02 K. The insert (b) shows the same fit but on a logarithmic scale while insert (a) show a fit to the straight power law equation (1) with the same value of β . One can qualitatively see that the fit only agrees at small values of t and the data clearly deviate from the fit at larger values of t when the straight power law is used.

We were therefore motivated to more carefully examine the dependence of the fit on the inclusion of points far from the transition temperature. Fits were performed as a function of starting point using both the straight power law equation (1) and the power law with correction-to-scaling included Eq. (2) and the resulting plot of β as a function of initial temperature is shown in Fig. 2. Both fits were carried out using a fixed value of T_{sp} . The value of β is independent of starting point when the power law with correction to scaling is used. However, when the straight power law is used, β changes over the entire temperature range. The curves become progressively closer to agreement as $T \rightarrow T_{sp}$ but could not be extended beyond a T_{initial} of 13.8 K due to a lack of good statistics over such a small temperature interval. None-

FIG. 2. The dependence of β on the temperature at which the fit was initialized for both the straight power law and the power law with correction-to-scaling included. Both curves use a constant fixed value of T_{sp} .

theless, there is quite reasonable agreement between the two values near T_{sp} and the analysis with the correction to scaling term included seems to be quite robust.

The value of the critical exponent β is also strongly influenced by the choice of T_{sp} and this dependence was also examined in detail. Figure 3 shows a plot of the goodness-of-fit parameter χ^2 and the critical exponent β as a function

FIG. 3. The dependence of the goodness-of-fit parameter $\chi^2 = \sum_i [\log(I_{\text{calc}}(T_i)) - \log(I_{\text{obs}}(T_i))]^2$ on T_{sp} along with the corresponding variation of the critical exponent β .

of the chosen value of T_{sp} from a fit to the power law with correction to scaling included. There is a pronounced minimum in the χ^2 curve at a T_{sp} of 14.06 K with a corresponding β value of 0.36.

CONCLUSIONS

Following this careful measurement and analysis, we conclude that the spin-Peierls transition in CuGeO_3 is a continuous transition which is characterized by a transition temperature of 14.06 ± 0.02 K and a critical exponent β of 0.36 ± 0.03 . This value of β is in agreement with conventional 3D behavior but is in closest agreement with 3D Heisenberg and XY behavior (predicted values of β : 3D Ising=0.326, 3D XY=0.345, and 3D Heisenberg=0.367¹⁰). It is important to note that this value of β differs substantially from the value of 0.26 (consistent with tricritical behavior) obtained from previous neutron diffraction work.⁵ We believe that this difference can be attributed to improper consideration of the effect of the inclusion or removal of data points well away from T_{sp} . Indeed, if we use data from a similar range of reduced temperature as was used by Harris *et al.*,⁵ we obtain a similar estimate of β . However, such a fit produces a clear deviation from the data near the transition temperature.

^{35}Cl nuclear magnetic resonance (NMR) and relaxation measurements have been performed in stacked $\text{Sr}_2\text{CuO}_2\text{Cl}_2$ single crystals with Néel temperature $T_N=257$ K for two crystal orientations with respect to the applied field: $\mathbf{H}\parallel\mathbf{c}$ and $\mathbf{H}\perp\mathbf{c}$. All the parameters of ^{35}Cl NMR are found to exhibit a strong orientation dependence varying in temperature. In particular, the unconventional anisotropy and strong temperature dependence of the ^{35}Cl nuclear spin-spin relaxation rate, T_2^{-1} , are presented and discussed in terms of a crossover of the Cu^{2+} spin dynamics from Heisenberg to XY-like correlation for $T\rightarrow T_N^+$. The onset of anisotropic broadening and shift of the ^{35}Cl NMR line was observed well above T_N , which is in agreement with the previous results. © 1996 American Institute of Physics. [S0021-8979(96)39308-0]

I. INTRODUCTION

The undoped layered perovskite system $\text{Sr}_2\text{CuO}_2\text{Cl}_2$ represents a very good model system for the spin $S=1/2$ two-dimensional (2D) square-lattice Heisenberg antiferromagnet (2DSLHA) with weak easy-plane anisotropy.¹ Recent neutron scattering studies² and ^{35}Cl NMR and susceptibility studies³⁻⁵ provide a quantitative comparison of theory and experiments regarding the temperature dependence of the intraplanar correlation length (ξ) of the Cu^{2+} spins above the Néel temperature $T_N=257$ K and the crossover effects associated with the XY anisotropy and the anisotropy induced by an external magnetic field.⁵ In particular, the ^{35}Cl nuclear spin-lattice relaxation rate T_1^{-1} (NSLR) in single crystals with $\mathbf{H}\parallel\mathbf{c}$ has revealed a divergent behavior for $T\rightarrow T_N^+$, indicating a crossover of the Cu^{2+} spin dynamics from Heisenberg to XY-like correlation at $T\approx 290$ K.

In this paper, we present additional evidence for the crossover effect obtained from measurements of ^{35}Cl nuclear spin-spin relaxation rate (T_2^{-1}). Furthermore, we present new data for the anisotropic broadening and shift of the ^{35}Cl NMR line occurring above T_N which agree with previous results⁴ and confirm the presence of field-induced two dimensional short range ordering above T_N .

II. EXPERIMENTAL RESULTS

The ^{35}Cl NMR experiments were carried out on a stack of single crystals of $\text{Sr}_2\text{CuO}_2\text{Cl}_2$ having a common tetragonal c axis using coherent Fourier transform spectrometers at 4.7 and 8.2 T (see Ref. 5 for experimental details). The ^{35}Cl ($I=3/2$) resonance line refers to the central transition only ($+1/2\leftrightarrow -1/2$).⁵

The results for the temperature dependence of the shift of the ^{35}Cl line with respect to NaCl aqueous solution are shown in Fig. 1 for two magnetic field intensities and two orientations. The results for the ^{35}Cl linewidth at half maximum are shown in Figs. 2(a) and (b). The measurements for $\mathbf{H}\perp\mathbf{c}$ are not reported for $T<T_N$ since the ^{35}Cl resonance line becomes very broad. The decay of the spin-echo signal was measured as a function of separation τ between two radio frequency (rf) pulses in an ordinary pulse sequence, $(\pi/2)_x - \tau - (\pi)_y$, with $\tau_{\pi/2}=2.5$ μs . The shape of the spin-echo decay was not a simple form such as a single exponential or a single Gaussian but could be fit by the product of two functions, an exponential, and a Gaussian:

$$M(t) = M(0) \exp\left(-\frac{t}{T_L}\right) \exp\left[-\left(\frac{t}{T_G}\right)^2\right]. \quad (1)$$

FIG. 1. ^{35}Cl NMR shift, K, vs temperature in stacked $\text{Sr}_2\text{CuO}_2\text{Cl}_2$ single crystals for two intensities and two orientations of the external magnetic field \mathbf{H} with respect to the crystal c axis.

FIG. 2. ^{35}Cl NMR linewidth $\Delta\nu$ at half maximum height vs temperature in stacked $\text{Sr}_2\text{CuO}_2\text{Cl}_2$ single crystals: (a) Linear-scale plot of $\Delta\nu$ for two magnetic field intensities. (b) Semilog plot of $\Delta\nu$ for $H=4.7$ T.

The results for the temperature dependence of the exponential component, T_L^{-1} , and of the Gaussian component, T_G^{-1} , of the spin-echo decay are shown in Figs. 3(a) and (b), respectively.

III. DISCUSSION

First, as can be seen from Fig. 3(b), the Gaussian contribution, T_G^{-1} , to the spin-spin relaxation rate is anisotropic and practically temperature independent. An approximate calculation of the Van Vleck second moment⁶ due to homonuclear ^{35}Cl nuclear dipolar interaction yields $(1/T_2)_{\text{dip}} = (\langle \Delta\nu^2 \rangle / 2)^{1/2} = 43 \text{ s}^{-1}$ for $\mathbf{H} \perp \mathbf{c}$ and $(1/T_2)_{\text{dip}} = 63 \text{ s}^{-1}$

FIG. 3. Plots of the ^{35}Cl nuclear spin-spin relaxation rate components for $H=4.7$ T. (a) The exponential component (T_L^{-1}) vs T . The curves are only guides for the eye. (b) The Gaussian component (T_G^{-1}) vs T . The lines are the average values of T_G^{-1} ; (dashed line) $(T_G^{-1})_{ab} = 107 \text{ s}^{-1}$, and (solid line) $(T_G^{-1})_c = 58 \text{ s}^{-1}$.

for $\mathbf{H} \perp \mathbf{c}$ in the case of a simple Gaussian shape of the spin-echo decay. The calculated values agree both in magnitude and in sign of the anisotropy with the experimental results. We conclude that the temperature independent Gaussian component of the spin-echo decay [see Eq. (1)] is due to nuclear dipolar interaction, i.e., $T_G^{-1} \equiv (1/T_2)_{\text{dip}}$. On the other hand, the exponential component of the spin-echo decay, T_L^{-1} , [see Fig. 3(a)] is indicative of a contribution due to the ^{35}Cl nucleus- Cu^{2+} electron spin interaction modulated by the fast Cu^{2+} spin dynamics and thus can give information on crossover effects. For weak time dependent fluctuations of the local field and in a time dependent perturbation theory, one can write for this contribution⁶

$$\frac{1}{T_L} = \frac{1}{2} \gamma^2 \int \langle h_z(t) \cdot h_z(0) \rangle dt + \frac{1}{2T_1}, \quad (2)$$

where $h_z(t)$ is the component of the local field parallel to \mathbf{H} at the ^{35}Cl site due to the Cu^{2+} magnetic moments. As it was discussed previously^{4,5} the dominant contribution to the ^{35}Cl hyperfine interaction comes from the dipolar and/or contact interaction of the ^{35}Cl nucleus with the first neighbor Cu^{2+} magnetic moment at distance d along the c axis. Thus, we can write for the hyperfine field

$$\mathbf{h} = \mathbf{h}_{\text{dip}} + \mathbf{h}_{\text{cont}} = \frac{1}{d^3} (-\mu_a \hat{a} - \mu_b \hat{b} + 2\mu_c \hat{c}) + A(\mu_a \hat{a} + \mu_b \hat{b} + \mu_c \hat{c}), \quad (3)$$

where \hat{a} , \hat{b} , and \hat{c} are the unit vectors of the crystal axes reference frame and $\mu_{a,b,c}$ are the instantaneous components of a Cu^{2+} nearest neighbor magnetic moment to a given ^{35}Cl nucleus and A is the contact hyperfine constant. By combining Eqs. (2) and (3), one has

$$\left(\frac{1}{T_L} \right)_c = \left(\frac{1}{2T_1} \right)_c + \frac{\gamma^2}{2d^6} \cdot 4J_{\parallel}(0) + \frac{\gamma^2 A^2}{2} J_{\parallel}(0) \quad (\mathbf{H} \parallel \mathbf{c}),$$

$$\left(\frac{1}{T_L} \right)_{ab} = \left(\frac{1}{2T_1} \right)_{ab} + \frac{\gamma^2}{2d^6} \cdot J_{\perp}(0) + \frac{\gamma^2 A^2}{2} J_{\perp}(0) \quad (\mathbf{H} \perp \mathbf{c}), \quad (4)$$

where $J_{\perp}(0) \equiv J_{aa}(0) = J_{bb}(0)$, $J_{\parallel}(0) \equiv J_{cc}(0)$, and $J_{\alpha\beta}(0) = \int_{-\infty}^{+\infty} \langle \mu_{\alpha}(t) \mu_{\beta}(0) \rangle dt$. Comparing the data in Fig. 3(a) with the values of $T_1^{-1} = 2W$ in Ref. 5 one has $T_L^{-1} \gg T_1^{-1}$ above T_N which implies $J_{\alpha\beta}(0) \gg J_{\alpha\beta}(\omega_L)$,⁵ where ω_L is the nuclear resonance frequency. Thus, by neglecting the first term in Eq. (4), one has $(T_L^{-1})_c = (4\gamma^2/2d^6 + \gamma^2 A^2/2) J_{\parallel}(0)$ and $(T_L^{-1})_{ab} = (\gamma^2/2d^6 + \gamma^2 A^2/2) J_{\perp}(0)$. Figure 4 shows the direct ratio $(T_L^{-1})_c / (T_L^{-1})_{ab}$ vs temperature. The saturating value of the ratio $(T_L^{-1})_c / (T_L^{-1})_{ab} \approx 5.5 \pm 1$ well above T_N is consistent with Eq. (4) for a relatively small contact hyperfine interaction A . As $T \rightarrow T_N^+$, $(T_L^{-1})_c$ decreases in agreement with the behavior expected if the longitudinal out-of-plane fluctuations, $J_{\parallel}(0)$, are progressively suppressed with decreasing temperature [see Figs. 3(a) and 4]. We conclude, consistent with the conclusion previously inferred from NSLR measurements,⁵ that the Cu^{2+} spin system crosses over from Heisenberg to XY-like behavior upon cooling toward T_N . Very close to T_N the NSLR is strongly enhanced.⁵ Thus, the

FIG. 4. The ratio $(T_L^{-1})_c / (T_L^{-1})_{ab}$ vs T . The curve is only a guide for the eye.

first term in Eq. (4) is no longer negligible and $(T_L^{-1})_{c,ab}$ are also enhanced. The fact that $T_L^{-1} \gg T_1^{-1}$ [i.e., $J_{\alpha\beta}(0) \gg J_{\alpha\beta}(\omega_L)$] well above T_N probably contains important information about the type of correlated spin-order in the system but it cannot be presently understood. One could speculate that very low frequency modes are present contributing to T_L^{-1} but not to T_1^{-1} or that the critical modes in this low-dimensional system have a diffusive character with consequent logarithmic divergence of the spectral density as $\omega \rightarrow 0$.⁷

The results for the ^{35}Cl NMR line shift and width are shown in Figs. 1 and 2, respectively. The linewidths, $\Delta\nu$, are in good agreement with previous results.⁴ Regarding the shifts, K , vs T , we can see a field independent enhancement of K in Fig. 1 for the applied field in the ab plane which could not be observed previously⁴ due to poorer quality of the single crystal stack available previously. As discussed previously,⁴ the enhancement and the anisotropy of $\Delta\nu$ cannot be explained by demagnetization effects nor by random ferromagnetic impurities. Also, the magnetic susceptibility displays a weak temperature dependence with no enhance-

ment close to T_N ; thus, the observed enhancement of $\Delta\nu$ and of K cannot be simply the result of the paramagnetism of the Cu^{2+} magnetic moments. On the other hand, the results could be explained qualitatively if one assumes that the application of the magnetic field in the ab plane stabilizes static two-dimensional short range order of the Cu^{2+} moments.⁴ It is interesting to note that the onset of the anisotropy in the line broadening occurs around the temperature at which $(T_L^{-1})_c$, i.e., the out-of-plane fluctuations, $J_{\parallel}(0)$, decrease most rapidly (see Fig. 4).

Finally, the magnitudes of the broadening, of the shift, of the NSLR, and spin-spin relaxation rates are too large to be accounted for by a "bare" dipolar interaction between ^{35}Cl and Cu^{2+} magnetic moments as in Eq. (4). It is quite likely that the partial covalent Cl-Cu bond induces an enhanced pseudodipolar interaction which we infer to be almost one order of magnitude larger than the "bare" dipolar interaction in order to explain the data.

Magnetic and nonmagnetic glass transitions in the Blume–Emery–Griffiths model with competing biquadratic interactions (abstract)

Daniel P. Snowman and Susan R. McKay

Department of Physics and Astronomy, University of Maine, Orono, Maine 04469-5709

The Blume–Emery–Griffiths model, a spin-1 Ising model with bilinear (J), biquadratic (K), and crystal field (Δ) terms, provides a general system for the analysis of both density and magnetic fluctuations. Using a Monte Carlo hard-spin mean-field approach,¹ we have calculated the phase diagrams resulting from a random bimodal distribution of biquadratic interactions, $K_{ij} = \pm K$, with equal probabilities. The quenched disorder in K competes with the propagation of long-range magnetic order and leads to two types of glassy ordered phases, magnetic and nonmagnetic. The variance in the site density over the lattice serves as an order parameter for the transition to these glassy phases. We compare the structure and overlaps of their low lying energy states with those of the three-dimensional Ising spin glass, determined using the same method.² The magnetic glass exhibits a much more gradual loss of overlap with its low-temperature state than the spin glass. The form of the overlap versus temperature curve in the vicinity of the critical temperature for the magnetic glass suggests that the system is fluctuating between a pair of ordered states, with one obtained from the other by flipping all spins, rather than sampling many different states. © 1996 American Institute of Physics. The three-dimensional RFIM: Existence of a tricritical point? (abstract)

Laura Hernandez and H. T. Diep

Groupe de Physique Statistique, Université de Cergy Pontoise, 49 Av. des Genottes, BP 8428, 95006 Cergy Pontoise, Cedex, France

The critical behavior of the RFIM has been a subject of controversy for a long time. After the qualitative analysis of Imry and Ma¹ and the rigorous proof given by Imbrie,² it is nowadays accepted that the lower critical dimension of the system is $d_1=2$. Though some general results exist in the mean field approach,^{3,4} the nature of the transition for the real system for $d>2$ remains less clear. In this work we study, using the Monte Carlo histogram technique and finite size scaling, the three-dimensional RFIM with a symmetric bimodal field distribution. Our results strongly suggest the existence of a tricritical point where the transition crosses over from a second-order transition at low but finite fields to a first-order transition for high fields, in contradiction with previous suggestions issued from standard Monte Carlo simulations.⁵ © 1996 American Institute of Physics. $m=3$ Ashkin–Teller-like cubic model on an FCC lattice

Ronald Fisch

Department of Physics, Washington University, St. Louis, Missouri 63130

Monte Carlo simulations have been used to study a model consisting of three Ising models with nearest neighbor exchange J on a face-centered-cubic lattice, which are coupled together by a constraint. The constraint requires that the vector sum of the four spins located at the corners of any elementary tetrahedron of the lattice not add to zero. Finite-size scaling analysis of the Monte Carlo results for $L \times L \times L$ lattices with $L=16, 32$, and 64 has been used to find that $T_c/J=10.84 \pm 0.01$. The finite-size scaling functions for the magnetization and magnetic susceptibility near T_c are consistent with standard $m=3$ Heisenberg critical exponents, as predicted by renormalization group theory. Strengthening the four-spin constraint increases the value of the effective negative Ashkin–Teller four-spin coupling, and drives T_c to infinity. © 1996 American Institute of Physics. [S0021-8979(96)39408-7]

The role of topological defects in low-temperature phases which possess a spontaneously broken continuous symmetry is a subject of long-standing and continuing interest.^{1,2} One way to learn about the effects of these defects is to study toy models in which they have been reduced in number or removed altogether.^{3–8} Completely removing the string defects from a three-dimensional XY model^{3,4,8} or the point defects from a three-dimensional Heisenberg model^{5,6} forces the system to remain in the broken-symmetry phase at all temperatures.

A point demonstrated nicely by the model of Kamal and Murthy⁷ is that the inability of the system to get out of the broken-symmetry phase without creating defects does not prove that these defects drive the phase transition. Kamal and Murthy showed that in a three-dimensional Heisenberg model where nearest-neighbor pairs of point defects were allowed the transition to the high temperature paramagnetic phase did occur. These nearest-neighbor defect dipoles do not change the long-range topological properties of the system. Thus, we cannot properly attribute the failure to reach the symmetry-restored phase when defects are prohibited to the topological aspect of the problem.

The way in which the defects are removed from a model is by attaching a large (or infinite) energy to each spin configuration which contains a defect. It is inevitable that this procedure also induces strong interactions between the spin-wave excitations. Thus, from a renormalization-group perspective, varying the defect fugacity is essentially equivalent to varying the four-spin interaction potential. (In the context of the two-dimensional XY model, these two quantities are related through a duality transformation.⁹)

In order to make this point explicit, in the work presented here we will show that by directly varying the strength of a four-spin interaction for a three-dimensional three-component spin model, we can achieve results which are similar to those found when the defect fugacity is varied. Furthermore, we can obtain qualitatively similar results in a four-component spin model,¹⁰ for which there are no topological defects.

The Hamiltonian we study is of the form

$$H = -J \sum_{\langle ij \rangle} \mathbf{S}_i \cdot \mathbf{S}_j - J_4 \sum_{\text{tet}} f(|\mathbf{S}_i + \mathbf{S}_j + \mathbf{S}_k + \mathbf{S}_l|^2), \quad (1)$$

where each \mathbf{S} is a classical fixed-length three-component spin variable which can assume the eight values $(\pm 1, \pm 1, \pm 1)$. The sites i form a face-centered cubic (fcc) lattice, $\langle ij \rangle$ is a sum over neighbor pairs, and tet is a sum over sets of four spins which form an elementary tetrahedron of the lattice. We assume that J and J_4 are positive.

Equation (1) is qualitatively similar to the $m=3$ Ashkin–Teller model studied by Grest and Widom,¹¹ although the form of the four-spin coupling is different. For simplicity, we choose our four-spin potential to have a hard-core form. Define

$$r_4 = \left| \sum_{i=1}^4 \mathbf{S}_i \right|^2. \quad (2)$$

Then we choose $f(r_4)$ to be of the form

$$f(r_4) = \infty \text{ if } r_4 \leq R \text{ and } 0 \text{ otherwise.} \quad (3)$$

When $R < 0$ (or $J_4 = 0$), the model reduces to three decoupled Ising models. The critical temperature of the Ising model on an fcc lattice¹² is approximately $T_c/J=9.7969$. The form of Eq. (3) forces the magnetization, and therefore T_c , to be a monotonically increasing function of R .

Because the model restricts each \mathbf{S} to eight vectors corresponding to the corners of a cube, r_4 can only assume a finite set of integer values: $\{0, 4, 8, 12, \dots, 48\}$. The number of different states of four spins is $8^4=4096$. The number of these which have $r_4=0$ is 216, and the number which have $r_4=4$ is 864. Thus, setting $R=0$ gives a rather weak perturbation of the Ising model, but $R=4$ is substantially stronger.

As R is increased the entropy of a paramagnetic phase, which has no long range order, is reduced relative to the entropy of a ferromagnetic phase. For $R=4$ the paramagnetic phase is only stable at very high T . For $R=8$ there is never a stable paramagnetic phase. In this case, there is a first order phase transition at about $T/J=12.9$, to a phase in which one of the spin components becomes almost completely ordered, while the remaining components are disordered. This phase is called phase III by Grest and Widom,¹¹ and occurs for negative values of the four-spin coupling in the standard Ashkin–Teller model. When one spin component is fully ordered, then r_4 must be ≥ 16 . In the large m limit of our model, phase III becomes more stable than the paramagnetic

FIG. 1. Specific heat for the $m=3$ cubic model with $R=0$ on $L \times L \times L$ fcc lattices.

phase at high T when $R=16$. Having one component ordered allows the remaining components to ignore the four-spin potential. The net result of this is that phase III has a higher entropy than the paramagnetic phase in this range of R . Of course, when R becomes very large all of the components must remain ordered at all T , and the model becomes uninteresting.

Although there is no precise correspondence, increasing the value of R is similar to increasing the hedgehog fugacity in the model of Lau and Dasgupta.^{5,6} We could increase the similarity by allowing each \mathbf{S} to assume all values on the surface of a sphere, so that r_4 would have a continuous range of values. That, however, is not the path we will follow here.

FIG. 2. Finite-size scaling of the magnetization for the $m=3$ cubic model with $R=0$ on $L \times L \times L$ fcc lattices. The vertical axis is scaled logarithmically, $t = T/10.84 - 1$, $\nu = 0.705$ and $\beta = 0.3645$.

FIG. 3. Finite-size scaling of the longitudinal susceptibility for the $m=3$ cubic model with $R=0$ on $L \times L \times L$ fcc lattices. The vertical axis is scaled logarithmically, $t = T/10.84 - 1$, $\nu = 0.705$, and $\gamma = 1.386$.

In the remainder of this work we will describe the results of a detailed Monte Carlo study of the discretized model for the case $R=0$.

A renormalization group analysis¹³⁻¹⁵ predicts that Eq. (1) with a weak ferromagnetic four-spin term like the one we get for $R=0$ should have a ferromagnetic critical point which is the universality class of the $m=3$ Heisenberg fixed point. This prediction has been verified experimentally.¹⁶ A Monte Carlo study can give detailed information which is not easy to obtain in a laboratory experiment.

The computer program used was a simple adaptation of the standard Metropolis Monte Carlo algorithm. All of the energies in the problem are integers, which allows for efficient computation. An attempt to flip a spin consisted of the following procedure. First, one of the eight possible states of a spin was chosen using a pseudorandom number generator. If this state was identical to the existing state of the spin being tested, a different state was chosen. Then, a decision between the existing state and the proposed state was made using the Metropolis algorithm with a second, different random number generator. One Monte Carlo step (MCS) consisted of a sweep through the entire lattice using this procedure. The spin lattice was stored as an $L \times L \times L$ integer array in which only alternate sites were used. Although this might seem wasteful, the actual size of the array was small enough so that convenience was the overriding factor. The sizes used were $L=16$, 32 , and 64 . Averaging was typically carried out over $10\,000$ MCS at each temperature, after allowing time for equilibration. Somewhat longer runs were used for the $L=64$ case near T_c .

Since a crossover from Ising to Heisenberg critical behavior is involved, it is not necessarily true that the lattice sizes accessible to the computer will show the $m=3$ behavior. This requires that the strength of the four-spin term be enough to shift the behavior far enough away from the Ising case so that the crossover scale is not too large. Setting $R=0$

FIG. 4. Finite-size scaling of the cubic anisotropy function Φ defined in Eq. (6), for the $m=3$ cubic model with $R=0$ on $L \times L \times L$ fcc lattices. $t=T/10.84-1$ and $\nu=0.705$.

is satisfactory for this purpose. It turned out that $L=16$ was the smallest useful lattice size, because of the crossover.

Figure 1 shows the specific heat for the three lattice sizes. Most of the specific heat is contained in a broad peak centered at $T/J \approx 9$. This peak may be thought of as the remnant of the Ising behavior. As L gets large, we see a shoulder develop at T_c , which is approximately 10% above the Ising T_c . In order to study the critical properties, we will use finite-size scaling theory.¹⁷ As we can see from Fig. 1, most of the specific heat is in the broad background. Thus, we would need data from even larger lattices to get useful information about critical behavior from the specific heat.

The finite-size scaling functions¹⁷ for the magnetization and the (longitudinal) magnetic susceptibility (per spin) are given by

$$M(L, T) = L^{-\beta/\nu} Q_M(tL^{1/\nu}) \quad (4)$$

and

$$\chi(L, T) = L^{\gamma/\nu} Q_\chi(tL^{1/\nu}), \quad (5)$$

where $t = T/T_c - 1$. The values of the critical exponents were set equal to the standard renormalization group field theory values¹⁸ for the $m=3$ Heisenberg critical point. Thus, the

only adjustable parameter is T_c , which is estimated to be $10.84 \pm 0.01 J$. The scaling forms, Eq. (4) and Eq. (5), are used to display the data from the $L=16, 32$, and 64 lattices in Figs. 2 and 3, respectively. We see that the overlap of the data for different values of L is good in a fairly broad region near T_c . The breakaway of the $L=16$ data at low temperatures is caused by the crossover from Ising behavior.

In order to study the angular distribution of the magnetization, we calculate the function

$$\Phi(L, T) = \frac{L^3}{2} \sum_{\alpha=1}^3 \left(\sum_i S_i^\alpha \right)^4 / \left(\sum_{\alpha=1}^3 \left(\sum_i S_i^\alpha \right)^2 \right)^2. \quad (6)$$

For large L , Φ goes to $1/3$ for $T < T_c$ and $3/5$ for $T > T_c$. As demonstrated in Fig. 4, the transition region near T_c has a width proportional to $L^{-1/\nu}$. Therefore, the correlation length exponent for transverse fluctuations is the same as for longitudinal fluctuations. We do not find a new critical exponent associated with Φ , and two exponents suffice for the description of the asymptotic critical behavior.

Overall, we can say that the data are entirely consistent with the prediction that the critical behavior for $R=0$ is described by the $m=3$ Heisenberg critical point. In work which will be described elsewhere,¹⁰ we have also verified the prediction¹³⁻¹⁵ that the critical behavior of the $m=4$ case of Eq. (1) is described by a stable $m=4$ cubic fixed point.

Phase transitions in disordered systems: Exactly solvable model

D. Nicolaides and A. A. Lisyansky

Department of Physics, Queens College of CUNY, Flushing, New York 11367

The critical behavior at phase transitions of random systems is studied within the framework of an exactly solvable model which takes into account interactions of fluctuations with equal and opposite momenta. Using the replica method, the dimensional reduction by 2 for the ϕ^4 model with a quenched random field is explicitly shown. Phase transitions in systems with two interacting order parameters which in addition are coupled to two independent random fields are also studied. In the absence of random fields the model demonstrates fluctuation induced phase transitions of the first order for spacial dimension $d < 4$. In random systems with only one quenched random field present, second order phase transitions are restored. Two random fields suppress any phase transitions for $d < 4$. For interaction of an infinite range, the model demonstrates the mean field critical asymptotics independently of dimensionality or the presence of random fields. © 1996 American Institute of Physics. [S0021-8979(96)39508-3]

Within the last two decades there has been considerable interest in the critical behavior of systems with quenched disorder.¹⁻⁶ In the present paper, we investigate such systems within the framework of an exactly solvable model that takes into account interaction of fluctuations with equal and opposite momenta. This model is very convenient to use in investigating critical phenomena in complex systems. Even though in its simplest version it has the same critical asymptotics as the spherical model,^{7,8} it explicitly demonstrates major qualitative results that have been obtained within renormalization group theory including fluctuation induced first order phase transitions.^{9,10} The renormalization group and the model lead to a similar critical behavior for phase transitions in orthorhombic high T_c superconductors with d pairing¹¹ and for oxygen ordering near a structural phase transition in Y-Ba-Cu-O.¹² Below we show that the model also demonstrates a dimensional crossover¹⁻⁴ for systems under a random quenched field. Also, we show that the fluctuation induced first order phase transition in systems with coupled order parameters¹⁰ is replaced by a continuous one in the presence of a random field.

We consider a system described by the Ginzburg-Landau functional

$$H = \frac{1}{2} \int d^d x \left[\tau S^2(\mathbf{x}) + c(\nabla S(\mathbf{x}))^2 + \frac{g}{4} S^4(\mathbf{x}) - h S(\mathbf{x}) - h(\mathbf{x}) S(\mathbf{x}) \right] \quad (1)$$

where $S(\mathbf{x})$ is a scalar order parameter, $\tau \propto T - T_c$, h , and $h(\mathbf{x})$ are constant and random fields, respectively. The free energy averaged with respect to a distribution of the random field can be evaluated with the help of the replica method.^{13,14} Assuming that $h(\mathbf{x})$ is a δ -correlated random variable, $\langle h(\mathbf{x}) h(\mathbf{x}') \rangle = B \delta(\mathbf{x} - \mathbf{x}')$, and $\varphi(\mathbf{x})$ is a replicated n -component vector order parameter, we derive an effective functional $H_{\text{eff}}[\varphi]$,

$$H_{\text{eff}} = \frac{1}{2} \int d^d x \left[\tau |\varphi(\mathbf{x})|^2 + c(\nabla \varphi(\mathbf{x}))^2 + \sum_{i=1}^n \left[\frac{g}{4} \varphi_i^4(\mathbf{x}) - h \varphi_i(\mathbf{x}) \right] - B \left(\sum_{i=1}^n \varphi_i(\mathbf{x}) \right)^2 \right]. \quad (2)$$

The free energy can be calculated exactly if we split interaction terms in Eq. (2) as follows:

$$\int d^d x \varphi_i^4(\mathbf{x}) \rightarrow \frac{1}{V} a^2[\varphi_i], \quad a[\varphi_i] = \int d^d x \varphi_i^2(\mathbf{x}). \quad (3)$$

Equation (3) implies that the model considers interactions of fluctuations with equal and antiparallel momenta only, and transfers the ϕ^4 model into the universality class of the spherical model.^{7,8} The model then uses a transformation analogous to that of Hubbard-Stratonovich so the partition function is read

$$Z = \int \prod_{i=1}^n (D\varphi_{iq} dx_i dy_i) \exp \left[-\frac{V}{2} \sum_{i=1}^n \left(\tau x_i + \frac{g}{4} x_i^2 - x_i y_i - \frac{h}{V} \varphi_{i0} \right) - \frac{1}{2} \sum_{i=1}^n \sum_{\mathbf{q}} |\varphi_{iq}|^2 (y_i + c q^2 - B) + \frac{B}{2} \sum_{\mathbf{q}} \sum_{i \neq j} \varphi_{iq} \varphi_{j-\mathbf{q}} \right]. \quad (4)$$

After the diagonalization with respect to indices i and j functional integrals in Eq. (4) can be calculated as

$$Z = \int \left(\prod_{i=1}^n dx_i \right) dy \exp \left[-\frac{V}{2} F(x_i, y, h) \right], \quad (5)$$

$$F(x_i, y, h) = \sum_{i=1}^n \left[t x_i + \frac{g}{4} x_i^2 - y x_i \right] - (1-n) f_d(y; c) + f_d(y - nB; c) - \frac{nh^2}{y - nB}, \quad (6)$$

where t is the renormalized trial critical temperature given by $t = \tau + g/2 S_d(2\pi)^{-d} \theta_d(\Lambda)$,

$$\theta_d(\Lambda) = \frac{S_d}{(2\pi)^d} \begin{cases} \frac{\Lambda^{d-2}}{c(d-2)}, & d \neq 2 \\ \frac{1 + \ln(c\Lambda^2)}{2c}, & d = 2 \end{cases}$$

$f_d(y; c)$

$$= \frac{S_d}{(2\pi)^d} \begin{cases} \frac{\pi y^{d/2}}{dc^{d/2} \sin(\pi d/2)} \equiv \kappa(c) y^{d/2}, & d \neq \text{even} \\ \frac{1}{d} \left(-\frac{y}{c} \right)^{d/2} \ln y, & d = \text{even} \end{cases} \quad (7)$$

Λ is the cutoff momentum, and S_d the surface area of a d -dimensional sphere. In the thermodynamic limit, $V \rightarrow \infty$, the saddle point of the integrals in Eq. (5) gives an exact solution for the partition function.

The disorder averaged free energy and the order parameter Φ are given, respectively, by the expressions

$$F_{av} = \lim_{n \rightarrow 0} \frac{1}{n} F(x_i, y, h), \quad \Phi = -\frac{\partial F_{av}}{\partial h} = \lim_{n \rightarrow 0} \frac{h}{y(h)}, \quad (8)$$

with x_i and y defined by the equations $\partial F / \partial x_i = 0$ and $\partial F / \partial y = 0$. This system of $n+1$ equations can be reduced to just one equation for y . The latter equation should be expanded in powers of n up to the first order. The resulting equation for y can be written in terms of Φ when Eqs. (8) are used:

$$\begin{aligned} \Phi^2 + \frac{2t}{g} - \frac{2}{g} \frac{h}{\Phi} + \frac{(-1)^{d/2}}{c^{d/2}} \left(\frac{h}{\Phi} \right)^{(d-2)/2} \left[\frac{1}{d} + \frac{1}{2} \ln \left(\frac{h}{\Phi} \right) \right] \\ - \frac{(-1)^{d/2} B(d-2)}{2c^{d/2}} \left(\frac{h}{\Phi} \right)^{(d-4)/2} \left[\frac{1}{d} + \frac{1}{d-2} \right. \\ \left. + \frac{1}{2} \ln \left(\frac{h}{\Phi} \right) \right] = 0, \quad d = \text{even}, \end{aligned} \quad (9a)$$

$$\begin{aligned} \Phi^2 + \frac{2t}{g} - \frac{2}{g} \frac{h}{\Phi} + \frac{\kappa(c)}{2} \left(\frac{h}{\Phi} \right)^{(d-2)/2} - \frac{B}{4} \kappa(c)(d-2) \\ \times \left(\frac{h}{\Phi} \right)^{(d-4)/2} = 0, \quad d = \text{noneven}. \end{aligned} \quad (9b)$$

When $t=0$ it becomes obvious from Eqs. (9) that in the limit

$h \rightarrow 0$ there are no solutions for Φ when $d \leq 4$. When $4 < d < 6$ the third and fourth terms in Eq. (9b) can be omitted because they become of a smaller order in h compared to the last term. After this the equation gives the same critical asymptotics as the "pure" model with the lower dimension $2 < d' (=d-2) < 4$. Namely, for critical exponents β and δ we have $\beta = 1/2$, $\delta = (d'+2)/(d'-2)$. When $d > 6$ in the limit $h \rightarrow 0$ only the first three terms in Eqs. (9) survive, and we arrive at the mean field critical exponents. Finally, for $d=6$ ($d'=4$) Eq. (9a) provides logarithmic corrections to the field asymptotic of the order parameter, $\Phi \propto [h \ln(ch)]^{1/3}$. So, the model explicitly demonstrates the dimensional crossover in the presence of quenched random fields.¹⁻⁴ It may seem contradictory that the model with the one-component order parameter has a lower critical dimension $d_c=4$. Indeed, functional (1) corresponds to the random-field Ising model with $d_c=2$. However, after the reduction equation (3), the model belongs to the spherical model universality class which has $d_c=4$.

Parameter $c^{1/2}$ represent the radius of interactions in the original system. Setting $c \rightarrow \infty$ (or $\kappa=0$) we suppress fluctuations. In this case, one can see from Eqs. (9) that a second order phase transition is restored and critical exponents become the same as the mean field ones independently of dimensionality or the presence of random fields.

Now, we consider the critical behavior of systems with two coupled scalar order parameters, which also are under the influence of two random fields. The Ginzburg-Landau functional is

$$\begin{aligned} H[S_1, S_2] = \frac{1}{2} \int d^d x \left\{ \sum_{i=1}^2 \left[\tau_i S_i^2(\mathbf{x}) + c_i (\nabla S_i(\mathbf{x}))^2 \right. \right. \\ \left. \left. + \frac{1}{4} g_i S_i^4(\mathbf{x}) + \frac{1}{2} w S_1^2(\mathbf{x}) S_2^2(\mathbf{x}) \right. \right. \\ \left. \left. - 2 \sum_{i=1}^2 [h_i S_i(\mathbf{x}) + h_i(\mathbf{x}) S_i(\mathbf{x})] \right\}. \end{aligned} \quad (10)$$

After following steps similar to those described above, we find two equations for the n -dimensional ($n \rightarrow 0$) order parameter Φ_i ($i=1,2$):

$$\begin{aligned} \Phi_i^2 - \frac{2g_i}{\Delta} \frac{h_i}{\Phi_i} + \frac{2g_{i'} t_{i'}}{\Delta} - \frac{2w t_{i'}}{\Delta} + \frac{2w}{\Delta} \frac{h_{i'}}{\Phi_{i'}} + \left\{ \frac{d}{2} \kappa(c_i) \left(\frac{h_i}{\Phi_i} \right)^{(d-2)/2} \right. \\ \left. - \frac{(-c)^{-d/2}}{d} \left(\frac{h_i}{\Phi_i} \right)^{(d-2)/2} \left[1 + \frac{d}{2} \ln \left(\frac{h_i}{\Phi_i} \right) \right] \right. \\ \left. + \left\{ \frac{-d(d-2)\kappa(c_i)}{4} B_i \left(\frac{h_i}{\Phi_i} \right)^{(d-4)/2} \right. \right. \\ \left. \left. - \frac{(-c)^{-d/2}}{d} B_i \left(\frac{h_i}{\Phi_i} \right)^{(d-4)/2} \left[d-1 + \frac{d(d-2)}{4} \ln \left(\frac{h_i}{\Phi_i} \right) \right] \right\} = 0 \right. \quad \text{for } \begin{cases} d = \text{noneven} \\ d = \text{even} \end{cases} \end{aligned} \quad (11)$$

where $i \neq i'$, $\Delta \equiv g_1 g_2 - w^2$ and $\kappa(c)$ is defined by Eq. (7). In case $B_1 = B_2 = 0$ and $2 < d < 4$, Eqs. (11) give a jumplike solution for Φ_i when $\Delta < 0$ and $h_i = 0$,¹⁰ so one has a fluctuation-induced first-order phase transition. When both B_1 and B_2 are not equal

to zero no solutions of Eqs. (11) exist when $h_i \rightarrow 0$ for $2 < d \leq 4$. So, the long range order is destroyed. Let us consider the case when there is only one random field, say $B_1=0$, $B_2 \neq 0$. For the sake of simplicity, we set $d=3$. The solutions of Eqs. (11) when $h_1=h_2=0$ are $\Phi_2=0$ and

$$\begin{aligned} \Phi_{i\pm}^2 = & \frac{3w|\kappa(c_2)|}{2g_1} \left[-\frac{3|\kappa(c_2)|\Delta}{8g_1} \right. \\ & \pm \sqrt{\left(\frac{3\kappa(c_2)\Delta}{8g_1}\right)^2 + t_2 - \frac{wt_1}{g_1}} - \frac{2t_1}{g_1} \\ & \mp \frac{3w|\kappa(c_2)|B_2}{4g_1 \sqrt{\left(\frac{3\kappa(c_2)\Delta}{8g_1}\right)^2 + t_2 - \frac{wt_1}{g_1}}} \end{aligned} \quad (12)$$

The solution Φ_{1+} corresponds to the lowest free energy. When $B_2=0$ and $\Delta < 0$ a nonzero value of Φ_{1+} appears by a jump at the temperature defined by the equation $[3\kappa(c_2)\Delta/8g_1]^2 + t_2 - wt_1/g_1 = 0$. However, as long as $B_2 \neq 0$, the dependence of Φ_{1+} on the temperature is no longer jumplike. Even though the solution of the equation $\Phi_{1+}^2=0$ is very cumbersome, it can be shown that near it Φ_{1+}^2 increases linearly from zero with decreasing temperature.

Besides, a nonequilibrium free energy corresponding to the functional equation (10) calculated in the framework of the model exhibits a dependence on the order parameter which is typical to second order phase transitions. So, in a system with two coupled order parameters the presence of a random field conjugated with one of them restores a phase transition of the second order.

Effect of exchange anisotropy on susceptibility of one-dimensional spin 1/2 ferromagnets

Ying Liu and John E. Drumheller

Physics Department, Montana State University, Bozeman, Montana 59717

We have studied several quasi-one-dimensional spin 1/2 ferromagnets ranging from Heisenberg to Ising anisotropy to test the Johnson and Bonner prediction that the low temperature thermodynamic behavior of these systems in external fields depends on the exchange anisotropy and that there are certain ranges of the anisotropy and fields in which bound magnons or spin waves dominate thermodynamic properties. The experimental results confirm that for the samples tested bound magnons dominate susceptibility across available range of the anisotropy ($\gamma < 1.05$) and for fields up to 9 T near the Heisenberg limit. © 1996 American Institute of Physics. [S0021-8979(96)39608-X]

INTRODUCTION

Nonlinear magnetic excitations called bound magnons¹ (BMs) have been shown by Johnson and Bonner (JB) theory² and earlier experiments³ to play an important role in determining the low temperature thermodynamic properties of the one-dimensional ferromagnetic system. The Hamiltonian is given by

$$H = -J \sum_i^N [S_i^z S_{i+1}^z + \gamma (S_i^x S_{i+1}^x + S_i^y S_{i+1}^y)] - g u_B h \sum_i^N S_i^z,$$

where J is the exchange interaction along a chain, and γ is an exchange anisotropy parameter which varies between the Ising limit ($\gamma=0$) and the isotropic Heisenberg limit ($\gamma=1$). The elementary excitations of this system, more easily identified in the Heisenberg case, are spin waves (SWs) with bound magnons resulting from nonlinear interactions between the spin waves. In particular, Johnson and Bonner² predicted that the low- T thermodynamic behavior of the system in external fields depends on the exchange anisotropy of the systems. There are several regions in field-anisotropy ($h-\gamma$) parameter space in which BMs or SWs dominate thermodynamic properties. The dominant behavior of the susceptibility is shown by Fig. 1. It can be seen that BMs are predicted to dominate over SWs throughout the range $0 < \gamma < 1$ and in most of the range of fields, except at very high fields. It is interesting to note that JB also predicted that for specific heat the situation is very different: spin waves give the main contribution in most of the range of $h-\gamma$ space and dominance of BMs only occurs in the range $0 < \gamma < 0.6$ with small fields.² In this paper, we present the experimental susceptibility results of several quasi one-dimensional spin 1/2 ferromagnets and compare these results to the JB prediction.

EXPERIMENTS AND RESULTS

The best example of a one-dimensional spin 1/2 Heisenberg ferromagnetic system reported up until now, as far as we know, is $(C_6H_{11}NH_3)CuCl_3$ (CHAC)⁴ and its bromine analog $(C_6H_{11}NH_3)CuBr_3$ (CHAB)⁴, both of which have strong intrachain exchange J of about 70 K and

weak interchain coupling $J'/J \sim 10^{-4}$. Compounds $(C_4H_8SO)CuCl_2(TMSO)$ ⁵ and $(CH_3)_4NCuCl_3(TMCuCl)$ ⁶ have middle range intrachain exchange of 40–50 K, and interchain $J'/J \sim 10^{-4}$. The compound $[(CH_3)_3NH]CuCl_3 \cdot 2H_2O(FeTAC)$ ³ has small J and J'/J , with Ising anisotropy. Anisotropy values γ of CHAB, CHAC, TMSO, TMCuCl, and FeTAC are 1.05, 0.995, 0.975, 0.92, and 0.05 (Ising), respectively.^{3–6} The preparation and structural analysis of these compounds have been previously reported.^{3–6} Most of the samples were provided by R. Willett, Chemistry Department, Washington State University.

The magnetic ac susceptibilities of crystal samples of CHAB, CHAC, TMSO, and powdered crystal sample of TMCuCl were measured from 4.2 to 35 K in an ac field $h=10$ Oe, frequency $f=80$ Hz and dc magnetic fields h of 0, 1, 2, 3, 4, and 5 T with both the applied fields along the easy-axis direction, which is perpendicular to the chain direction. All measurements were performed on the LakeShore Model 7225 AC Susceptometer/DC magnetometer. Measurements were fully calibrated and performed automatically through

FIG. 1. Regions and corresponding crossover boundary (Ref. 2) which determine bound magnon (BM) and spin wave (SW) dominance on susceptibility as a function of field h and anisotropy γ , where $H_0 = h/\gamma J$, $T_0 = T/\gamma J$. Dots represent experimental results.

data acquisition and control software packages. The system accuracies for both ac and dc measurements are $\pm 1\%$, and the temperature accuracy is ± 0.2 K. The high-field ac susceptibilities of crystal sample of TMSO and CHAC were measured in a ac field $h=10$ Oe, frequency $f=80$ Hz, and in high dc magnetic fields h of 7 and 9 T at the LakeShore laboratory, Westerville, Ohio. The ac susceptibility of FeTAC at fields 1, 2, 3, and 4 T was measured and reported earlier³ and high-field data were not available.

Temperature dependences of the ac susceptibilities of CHAB, CHAC, TMSO, TMCuC, and FeTAC all show typical rounded peaks of bound magnon effects as predicted by the JB theory. All the data are analyzed in term of contributions of BMs and SWs, by using the JB susceptibility model.² Fitting results show that BMs dominate over SWs on susceptibility in all of these compounds. The experimental results extracted from ac susceptibility data are plotted at fields $h=1, 2, 3, 4, 5, 7$, and 9 T and $\gamma=1.05, 0.995, 0.975, 0.92$, and 0.05, in the field-anisotropy parameter space in Fig. 1. Figure 1 shows that BMs dominate susceptibility

across available range of γ ($\gamma < 1.05$) and for fields up to 9 T near the Heisenberg limit, confirming the prediction of JB over this range.

The effects of bond randomness are studied for spin chains with excitation gaps in the pure case. Systems with enforced topological structure like the spin-1/2 chain with enforced dimerization and spin-1 chain in the Haldane gapped phase appear very stable against randomness. On the other hand, systems with spontaneously generated topological order like the spin-1/2 chain with spontaneous dimerization are found to be unstable even for weak randomness despite the gap. © 1996 American Institute of Physics. [S0021-8979(96)39708-6]

Theoretical work¹⁻⁴ on random quantum magnetic systems has shown that systems which behave critically in the absence of randomness are unstable against weak randomness. At low temperature these systems are in the so called random singlet (RS) phase,^{1,3} in which spins far apart in space form weakly bound singlet pairs in a random manner. The low-temperature thermodynamic properties of these systems are dominated by the weakly bound pairs and are universal,¹⁻³ e.g., the susceptibility diverges as $[T \log^2 T]^{-1}$ at low T , for the Heisenberg or XXZ spin-1/2 chain, independent of the details of the randomness.³ The disorder averaged spin-spin correlation functions also exhibit power law with universal exponents.³ There has been, however, very little work on effects of bond randomness on gapped antiferromagnets. We address this issue in the present paper.

Examples of gapped antiferromagnetic spin chains include integer spin chains in the Haldane phase,⁵ dimerized spin-1/2 chains,⁶ and spin chains with spontaneous dimerization.⁷ Naively one would expect such systems to be stable against weak randomness due to the existence of a gap, while strong enough randomness might drive them to a random singletlike phase. We find, however, this is not the case. The behavior of these systems depends *crucially* on their *topological structure*. Systems with enforced topological order, like the dimerized spin-1/2 chain and spin-1 chain in the Haldane phase, are found to be very stable and the topological order parameter survives even *strong randomness*. The low temperature thermodynamics is *nonuniversal* (as is seen experimentally⁸) in these systems, in contrast to the random singlet phase. On the other hand, systems with spontaneously generated topological order (like the spontaneously dimerized spin-1/2 chain) are unstable and are driven to the RS phase by weak randomness, even though such chains have gaps separating their ground and excited states.

We start with the spin-1/2 chain with spontaneous dimerization, and for convenience focus on the Majumdar-Ghosh (MG) model in the presence of weak randomness.⁷

$$H = \sum_i (J_i \mathbf{S}_i \cdot \mathbf{S}_{i+1} + K_i \mathbf{S}_i \cdot \mathbf{S}_{i+2}), \quad (1)$$

with J 's random but distributed near 1 and K 's near 1/2. When $J_i=1$ and $K_i=1/2$, this is the usual MG model with two degenerate spontaneously dimerized ground states and an excitation gap. We can separate H into two parts: $H = H_0 + H'$, with

$$H_0 = \sum_i K_i (\mathbf{S}_i \cdot \mathbf{S}_{i+1} + \mathbf{S}_i \cdot \mathbf{S}_{i+2} + \mathbf{S}_{i+1} \cdot \mathbf{S}_{i+2}), \quad (2)$$

$$H' = \sum_i \delta_i \mathbf{S}_i \cdot \mathbf{S}_{i+1}, \quad (3)$$

where $\delta_i = J_i - K_i - K_{i-1}$. The ground states of H_0 are the same as the ground states of the pure MG Hamiltonian, again with a double degeneracy, labeled as $|L\rangle$ and $|R\rangle$. H' , however, breaks the degeneracy and each term in it favors one state or the other. Hence, it is energetically favorable to separate the system into domains of $|L\rangle$ and $|R\rangle$ where they are favored by H' . In doing so, however, one creates domain walls which are unpaired edge spins. There is a finite energy cost (gap) from H_0 but the energy gain from H' always wins since it grows with the length of the domains as $|\delta| \sqrt{L}$, where $|\delta|$ is the typical strength of δ_i and L is the typical length of the domains. The energy gain is proportional to \sqrt{L} because δ_i is random. We, hence, find in the weak randomness limit the typical size of domains diverges as $L \sim 1/\delta^2$ and the density of domain walls is $N_d \sim \delta^2$. These unpaired spins in the domain walls dominate the low T thermodynamics since the bulk excitations within the domains are gapped. They are expected to have weak and random (due to the fluctuations in domain length) antiferromagnetic interactions. Hence, the low temperature thermodynamics should have the same form as the random Heisenberg chain with nearest neighbor interaction which is in the random singlet phase,³ for example, the susceptibility *diverges* at low T : $\chi \sim \delta^2/T |\log T|^2$. This should be contrasted with the pure case where χ *vanishes* exponentially at low T due to the existence of a gap. We, hence, find that the spontaneously

dimerized spin-1/2 chains are unstable against *weak* randomness, due to the facts that the ground state has a double degeneracy and the spinons carried by domain walls are weakly interacting and unconfined.

We next consider the dimerized spin-1/2 chain, where we find very different physics. The Hamiltonian for random antiferromagnetic XXZ chain is

$$H = \sum_i J_i [S_i^x S_{i+1}^x + S_i^y S_{i+1}^y + \Delta S_i^z S_{i+1}^z], \quad (4)$$

where S_i^α are spin-1/2 operators, J_i are (random) positive coupling constants, and $0 \leq \Delta \leq 1$. It can be shown that any $\Delta < 1$ flows to $\Delta = 0$ under renormalization group transformation.³ We hence concentrate on the cases of XX chain ($\Delta = 0$) and Heisenberg chain ($\Delta = 1$). In the presence of dimerization the distribution of the couplings J_i depends on whether i is even or odd. We write the distribution functions for even and odd J 's as $P_e(J, J_0)$ and $P_o(J, J_0)$, respectively. Here J_0 is the cutoff in the distribution function corresponding to the strongest bond in the system.

A powerful method to study such random antiferromagnets is the real space decimation renormalization group (RG) introduced by Dasgupta and Ma.¹ (See also Ref. 2). In this real space RG procedure we pick the bond in the system with the largest J (i.e., the strongest bond), say, J_{23} , between spins 2 and 3. Since this is such a strong bond, spins 2 and 3 are likely to form a singlet pair in the low energy (on scales much smaller than J_{23}) states of the system and become inert. The major physical effect of the existence of spins 2 and 3 is to mediate an effective coupling between their neighboring spins 1 and 4. For the XX chain, $\tilde{H}_{1-4} = \tilde{J}_{14}(S_1^x S_4^x + S_1^y S_4^y)$ where $\tilde{J}_{14} = J_{12} J_{34} / (J_{23}) + O(1/J_{23}^2)$. And for the Heisenberg chain, $\tilde{H}_{1-4} = \tilde{J}_{14} \mathbf{S}_1 \cdot \mathbf{S}_4$ where $\tilde{J}_{14} = J_{12} J_{34} / (2J_{23}) + O(1/J_{23}^2)$. The energy cutoff is then lowered to $\Omega = \max\{\tilde{J}\}$. The generated coupling is still between two nearest neighbor spins (since we have decimated spins 2 and 3 so spins 1 and 4 become nearest neighbors), so the renormalized Hamiltonian has the same form as the original one, except that the distribution of bonds is slightly different and the cutoff is lower. Thus, we can repeat this procedure and continue lowering the energy scale (cutoff) and renormalizing the bond distribution. As shown by Fisher,⁴ in the absence of dimerization ($P_e = P_o$), the distribution $P(J)$ flows toward an energy scale dependent universal random singlet (RS) fixed point distribution in the low energy limit

$$P(J, \Omega) = \frac{\alpha}{\Omega} \left(\frac{J}{\Omega} \right)^{-1+\alpha} \quad (5)$$

where Ω is the energy cutoff and $\alpha = 1/\log(J_0/\Omega)$ which goes to zero logarithmically. Hence, the distribution becomes more and more singular at $J=0$ as the energy scale decreases, implying that the decimated bonds are more and more likely to be *much* stronger than their neighbors, and the whole decimation procedure becomes asymptotically exact in the low energy limit. The consequence of this universal fixed point distribution is that the low temperature thermo-

dynamics and long distance spin-spin correlation function are universal for the undimerized random spin-1/2 chain.³

The situation is totally different when there is a small difference in the distributions for even and odd bonds, i.e., dimerization. We find that dimerization is a *relevant* perturbation at the RS fixed point, with eigenvalue $+1$,⁹ indicating that the difference in distributions *grows* as the energy scale decreases. Physically this is easy to understand. Assume that, on average, the odd bonds are slightly stronger than the even bonds. Thus, an odd bond is somewhat more likely to get decimated in the real space RG decimation procedure. This also results in decimation of two intermediate strength neighboring even bonds and generation of a *much weaker even bond*. Consequently, the even bond distribution picks up weight near $J=0$ faster than the odd bond distribution and the over all strength of even bonds decreases faster than the odd bonds. Thus, in the low energy limit, the system can be viewed as a trivially soluble collection of uncoupled spin pairs (isolated odd bonds). We refer to this phase as the random dimer (RD) phase.

After renormalization, the distribution of odd bonds takes the form

$$P_o(J) = \frac{\alpha}{\Omega_0} \left(\frac{J}{\Omega_0} \right)^{-1+\alpha} \Theta \left(1 - \frac{J}{\Omega_0} \right), \quad (6)$$

where Ω_0 is the energy scale at which the difference in strength of the even and odd bonds becomes significant. From the eigenvalue of the relevant perturbation we find for weak dimerization $\log(J_0/\Omega_0) \sim 1/\delta$, where δ parameterizes the strength of dimerization, and $\alpha = 1/\log(J_0/\Omega_0) \propto \delta \ll 1$. Knowing the distribution of odd bonds and treating the even bonds as unconnected, the thermodynamic properties in the low temperature limit can be easily calculated. As the temperature goes to zero, the spin susceptibility diverges like $\chi \sim T^{-1+\alpha}$, and the specific heat goes to zero like $C_v \sim T^\alpha$. They are qualitatively similar to those in the RS phase but nevertheless *nonuniversal*. The averaged spin-spin correlation function is short ranged, with the correlation length (distance between spins) $\xi \sim |\delta|^{-\nu}$ and $\nu = 2$. The existence of a divergent magnetic susceptibility away from the critical point is characteristic of a Griffiths phase. The divergent susceptibility arises from magnetically active gapless excitations. The random singlet phase, discussed by Fisher,³ also exhibits a divergent susceptibility. However, in the case of the random singlet state, the averaged spin-spin correlation function decays as $1/R^2$ at long distances so the system is critical and a divergent susceptibility is expected. If the initial dimerization is large, the flow begins far from the RS phase and the bond distribution of the stronger bonds does not flow to a power law and the gap does not close up. When this is the case, thermodynamic properties will depend strongly on the initial distribution and the susceptibility will remain finite.

The dimer phase has a novel kind of topological order that measures the dimerization of the chain, manifested in the following "string-topological correlation function" similar to that discussed in the context of spin-1 chain:¹⁰

$$T_{ij} = \langle \Psi_0 | S_i^z \exp \left[i \pi \sum_{i < k < j} S_k^z \right] S_j^z | \Psi_0 \rangle, \quad (7)$$

where $|\Psi_0\rangle$ is the ground state. For a completely dimerized ground state (where all the even bonds or all the odd bonds are set to be zero) $T_{ij} = -1/4$ if i is a left spin of a dimer and j is the right spin of a (possibly different) dimer. This is because every spin between i and j in the completely dimerized model is paired up with another spin between i and j . $T_{ij} = 0$ otherwise. Therefore, this special topological correlation function is long-ranged even though the ordinary spin-spin correlation function is short-ranged. For a general spin-1/2 chain with randomness, we introduce a topological order parameter

$$T = \lim_{j-i \rightarrow \infty} \overline{(T_{2i,2j-1} - T_{2i+1,2j})}, \quad (8)$$

where the overbar stands for average over randomness. Obviously T vanishes in the absence of dimerization. In the presence of dimerization, T measures the probability that the two end spins have survived decimation until the dimerization becomes large, and the low energy physics becomes that of the completely dimerized chain. We find⁹ for small δ , T scales like

$$T \sim -|\delta|^{2\beta} \text{sgn}(\delta), \quad (9)$$

with $\beta = \nu/2$, and $\text{sgn}(\delta)$ is positive if even bonds are stronger and negative if odd bonds are stronger.

It is important to notice that the topological order is not a spontaneous order like the spontaneous magnetization in a ferromagnet; it is actually dynamically *enforced* by the Hamiltonian. For example, the sign of the order parameter is determined by the sign of the dimerization, unlike spontaneous magnetization which can take any direction allowed by the symmetry. It reflects the fact that the Hamiltonian favors singlet pairs to be formed over even bonds, if the even bonds are stronger in general. In the absence of odd bonds the ground state is a trivial collection of singlet pairs over even bonds and the dimer or topological order is perfect. In the presence of odd bond couplings (but weaker than even bonds in general) both quantum and statistical fluctuations generate regions where singlet pairs are formed over odd bonds. Between regions of different topological structures there has to be a spin unpaired to its neighbors (a soliton). In the presence of dimerization, the energy cost of the "wrong region" (the area having singlets formed over the odd bonds in this case) is proportional to its length (at least at long enough length scales); hence, the unpaired spins are confined by a linear confining potential.¹¹ The confinement length in the weak dimerization limit is the length scale at which dimerization becomes significant under RG, which is also the spin-spin correlation length. We hence find that although the gap vanishes in the presence of strong randomness, the dimer phase is stable and the topological order persists due to the confinement of unpaired spins. This should be contrasted with the case of spontaneous dimerization. In that case the

two degenerate ground states also have finite topological order parameter, but it is a *spontaneous* order associated with the spontaneously broken translation symmetry, and is immediately killed upon introducing weak randomness and hence unconfined domain walls (solitons).

Our results for the dimerized spin-1/2 chain are likely to be applicable to the spin-1 chain in the Haldane phase. In the absence of randomness, they exhibit similar physical properties and can be connected to each other without closing the gap, implying they belong to the same phase.¹² It is natural to expect that they behave similarly in the presence of randomness.⁹ An explicit example that provides strong support to the above conjecture is the random version of the Affleck-Kennedy-Lieb-Tasaki model.¹³

$$H = \sum_i J_i \left[\mathbf{S}_i \cdot \mathbf{S}_{i+1} + \frac{1}{3} (\mathbf{S}_i \cdot \mathbf{S}_{i+1})^2 \right], \quad (10)$$

where $J_i > 0$. The exact ground state of this random model is identical to that of the pure model,¹³ i.e., a valence bond solid. Its excitation spectrum and thermodynamic properties will certainly depend on the distribution of J_i , yet the perfectly topologically ordered ground state (with short range spin-spin correlation function) is completely unaffected by randomness.

In summary, we have shown that the effects of randomness on gapped spin chains depend crucially on the topological structure of the system. Systems with enforced topological order like the dimerized spin-1/2 chain and the spin-1 chain in the Haldane phase are very stable, while systems without such enforced order like the spin-1/2 chain with spontaneous dimerization is unstable against weak randomness despite the gap.

The effect of substitution of Si to Ge in $\text{CuGe}_{1-x}\text{Si}_x\text{O}_3$ single crystals has been studied by magnetic susceptibility, Cu nuclear magnetic resonance, and neutron scattering measurements. The phase diagram in the (x, T) -plane is characterized by an initial rapid decrease of the spin-Peierls temperature, T_{SP} , on increasing x and by the occurrence of a three-dimensional long range ordered antiferromagnetic phase at $T = T_N$ in the range $0.005 \leq x \leq 0.05$. This phase diagram is qualitatively discussed. The neutron scattering data for $x = 0.007$ show that the dimerization which takes place below T_{SP} is not suppressed below T_N . © 1996 American Institute of Physics. [S0021-8979(96)39808-2]

I. INTRODUCTION

One-dimensional antiferromagnets (1D-AF) with isotropic short range interactions are of current interest because they exhibit large quantum effects. In particular, for the spin value $S = 1/2$, the quantum fluctuations and the magnetic energy can be reduced by the dimerization of the chain, if the latter can be easily distorted. The resulting exchange alternation gives rise to a singlet ground state separated from the first excited states by a gap. As the temperature is reduced, a spin-Peierls (SP) transition from a uniform phase to a dimerized phase (SP phase) occurs at a well defined temperature, T_{SP} . The recent discovery of a simple inorganic spin-Peierls compound, CuGeO_3 (Ref. 1) which can be grown in large single crystals and can accept various substitutions has renewed the field of experiments on the spin-Peierls transition. CuGeO_3 has an orthorhombic structure composed of linear chains of Cu^{2+} ions running along the c axis, and well separated from each other by Ge-O chains.² The $S = 1/2$ Cu^{2+} spins in a chain are equally spaced at high temperature and strongly coupled by antiferromagnetic intrachain interaction. The spin-Peierls transition which occurs at $T_{\text{SP}} = 14.3$ K is evidenced by a kink in the magnetic susceptibility.^{1,3} The structural transition to the dimerized state at T_{SP} has been revealed by x-ray and elastic neutron scattering.^{3,4} A rather attractive feature of CuGeO_3 is its ability to accept substitutions on the cationic sites. Investigations of such substituted materials have been carried out on samples containing either divalent ions substituted for Cu^{2+} such as Zn, Mg, Ni, and Mn,⁵⁻⁸ or Si substituted to Ge.⁹ We discuss here the effect of Si substituted for Ge on the phase diagram of $\text{CuGe}_{1-x}\text{Si}_x\text{O}_3$.

II. PHASE DIAGRAM OF $\text{CuGe}_{1-x}\text{Si}_x\text{O}_3$

The experimental investigation by susceptibility, Cu nuclear magnetic resonance and neutron scattering was carried out on $\text{CuGe}_{1-x}\text{Si}_x\text{O}_3$ with $0 \leq x \leq 0.1$ single crystalline samples cleaved along the (100) plane from large single

crystals several cm long, grown from the melt by a floating zone method associated with an image furnace.^{10,11} Details about the crystal growth and the Si concentration determination have been reported in a previous article.⁹

The temperature behavior of magnetic susceptibility of $\text{CuGe}_{1-x}\text{Si}_x\text{O}_3$ for $x \geq 5 \times 10^{-3}$ strongly differs from that of pure CuGeO_3 . In the concentration range 5×10^{-3} to 10^{-2} , when lowering the temperature, both χ_c and χ_b exhibit first a decrease, reminiscent of a spin-Peierls transition followed by an increase. Below a certain temperature T_N that we attribute to the onset of three-dimensional antiferromagnetic (3D-AF) order, χ_c exhibits a sharp drop and decreases toward zero whereas χ_b continues to increase but with a smaller slope. In the concentration range $2-5 \times 10^{-2}$, no indication of the SP transition can be detected from the temperature dependence of susceptibility whereas the transition to 3D-AF phase remains very clear. From these susceptibility data, the Néel temperature T_N at which χ_c vs T shows a sharp peak and the spin-Peierls temperature T_{SP} corresponding to inflection point above T_N have been determined and plotted as a function of x , leading to the phase diagram of Fig. 1. The Cu NMR experiments performed at 2 K in a dc magnetic field of 11 kOe applied along the c crystal axis have revealed a striking difference between the samples with $x = 0$ and 0.0025, and the samples with $x \geq 0.005$.⁹ While the first ones show one narrow line for each Cu isotope, the second ones show broad spectra splitted by the Cu hyperfine fields, corresponding to the antiferromagnetic long range order with the Cu spin direction along the c axis. Neutron scattering studies (Sec. III) and ultrasonic velocity measurements¹² performed on large single crystals with $x = 7 \times 10^{-3}$ are consistent with this phase diagram. The drastic initial decrease of T_{SP} with increasing x is well described by $T_{\text{SP}}(x)/T_{\text{SP}}(0) = 1 - \alpha x$ with $\alpha \approx 50$. For comparison a coefficient $\alpha \approx 14$ was found for Zn doping.⁵ In a wide range of Si concentrations, $5 \times 10^{-3} \leq x \leq 5 \times 10^{-2}$, the 3D-AF phase is observed at low temperature. T_N exhibits a maximum at $T_{N\text{max}} \approx 5$ K for $x = 0.015$.

FIG. 1. (x,T) -plane phase diagram of $\text{CuGe}_{1-x}\text{Si}_x\text{O}_3$ obtained from magnetic susceptibility measurements performed on single crystals. The three different regions limited by the phase separation lines correspond to the uniform phase (U) at high T , the spin-Peierls phase (SP) at low x and T , and the 3D long range ordered antiferromagnetic phase (AF) at low T and intermediate x values. The neutron determination of T_{SP} and T_N for $x=7.10^{-3}$ (Sec. III) is indicated by black square and circle.

III. NEUTRON SCATTERING STUDY OF $\text{CuGe}_{0.993}\text{Si}_{0.007}\text{O}_3$

The neutron scattering experiments were performed using three-axis spectrometers, DN1, installed on a thermal neutron beam of the Siloe reactor at CEN-Grenoble and IN12, installed on a cold neutron guide of the High Flux Reactor at ILL. In both cases, collimations $60'-60'-60'$ were used and the incident neutron wave vectors were fixed at $k_i=2.62$ and 1.5 \AA^{-1} , respectively. Neutron diffraction experiments performed on the DN1 spectrometer have clearly demonstrated the existence of superlattice peaks indexed with the propagation vector $\mathbf{k}_{SP}=(1/2,0,1/2)$, as in pure CuGeO_3 .³ Figure 2 depicts Q -scans along the c direction across scattering vector $\mathbf{Q}=(1/2,3,1/2)$, recorded at temperatures $T=11, 4$, and 1.5 K , which show the appearance of a resolution-limited peak below roughly 10 K . The temperature dependence of intensity at the maximum is given in Fig. 3 (curve b). Two remarks can be made concerning this curve.

FIG. 2. Elastic neutron scattering scans around the dimerization peak $(1/2, 3, 1/2)$ at 1.5 K ($T < T_N$), 4 K ($T \approx T_N$), and 11 K ($T > T_{SP}$) in $\text{CuGe}_{0.993}\text{Si}_{0.007}\text{O}_3$. The persistence of the dimerization below the Néel temperature, T_N , of 3D-AF long range order is clearly observed.

FIG. 3. Magnetic susceptibility and neutron scattering peak intensities vs the temperature, T , in a single crystal of $\text{CuGe}_{0.993}\text{Si}_{0.007}\text{O}_3$. Curves a, b, and c, respectively, correspond to χ_c , intensity of the dimerization peak $(1/2, 3, 1/2)$ and intensity of the 3D-AF Bragg peak $(0,1,1/2)$.

First, the transition is relatively “smooth” and is characterized by an up-turned curvature, probably due to a distribution of transition temperature in the sample. Our experimental data are consistent with a transition temperature ranging from 8.5 to 10 K , with an average value of 9.2 K in good agreement with susceptibility measurements on the same sample, Fig. 3 (curve a). This broadening is very likely related to a small inhomogeneity in the Si content, which amounts from our data to $x=0.007 \pm 0.001$. More interestingly, the intensity of dimerization peaks increases continuously down to about 4 K , below which the signal starts to decrease slightly. This is precisely the temperature at which χ_c exhibits a maximum, reflecting the appearance of 3D-AF long range ordering, Fig. 3. This interpretation has been further confirmed by studying the temperature dependence of superlattice peak $(0,1,1/2)$, which in fact corresponds to the minimum in energy of the excitation spectrum in pure CuGeO_3 . Figure 3 (curve c) shows the variation on temperature of the $(0,1,1/2)$ peak, obtained with the IN12 spectrometer. Quite unambiguously, a magnetic Bragg peak appears below $T_N \approx 4 \text{ K}$, characteristic of a 3D antiferromagnetic ordering described by the wave vector $\mathbf{k}_{AF}=(0,1,1/2)$. Above T_N , quasi-1D correlations subsist, which coexist with the dimerized phase up to T_{SP} , above which a more classical magnetic behavior is recovered. So, below T_N the dimerized phase persists (at least partly), coexisting with the 3D antiferromagnetic phase. The important point is that these two phases seem to coexist *independently one from each other*, as if a true “phase separation” was present in the system. Within this interpretation, the slight decrease of the $(1/2,3,1/2)$ intensity observed below T_N may be associated with a decrease of the population of dimerized domains. Inelastic neutron scattering experiments¹³ have confirmed this interpretation, by showing that the spin-Peierls gap associated with the dimerized phase is unchanged when crossing T_N , whereas the intensity of this mode increases slightly.

IV. DISCUSSION

The phase diagram of Fig. 1 clearly reflects the competition between the SP gap, Δ , which tends to induce a non-magnetic SP phase and the interchain interaction, J' , which tends to induce a long-range ordered 3D-AF phase. The stable phase at $T=0$ is determined by a balance between Δ and the effective 3D interaction, $E' = zJ'\xi_0/d$ where z is the number of neighboring chains, ξ_0 the 1D correlation length, and d the chain parameter. The effect of Si substitution is to reduce Δ , as evidenced by the drastic decrease of T_{SP} and by inelastic neutron scattering data on $\text{CuGe}_{0.993}\text{Si}_{0.007}\text{O}_3$:¹³ $\Delta=1.4$ meV instead of 2.1 meV in pure CuGeO_3 .^{14,15} Since ξ_0 is expected to be inversely proportional to Δ , the ratio E'/Δ should increase as $1/\Delta^2$ which strongly favors the 3D-AF phase. Indeed a maximum value of T_N is observed for $x=0.02$ which corresponds to the vanishing of the gap, $\Delta(x)$, for a linear dependence on x . With further increase of x , one can expect that the lattice defects reduce ξ_0 and thus reduce T_N .¹⁶ This simple physical picture can be applied to other kinds of substituents like Zn. This explains the striking similarity between the observed phase diagrams for Si and Zn doped CuGeO_3 , the relevant difference being in the $\Delta(x)$ dependence. It is also supported by recent calculations on a two-dimensional array of chains with alternating intrachain exchange.¹⁷ These calculations show that the dimerized phase can undergo long range AF order when the exchange alternation parameter which governs the size of the gap lies below a critical value. This is in agreement with the neutron experiments showing the persistence of the chain dimerization below T_N .

In summary, we have shown that Si substitution in CuGeO_3 has a drastic effect on the spin-Peierls transition. At low temperature, a long range ordered antiferromagnetic phase is observed in a wide range of Si concentrations, in

good agreement with the theoretical predictions. Its existence has been confirmed by neutron scattering experiments on a $\text{CuGe}_{0.993}\text{Si}_{0.007}\text{O}_3$ single crystal, which have shown that the dimerization is not suppressed below T_N .

$\text{Fe}_3\text{O}_4/\text{NiO}$ multilayers exhibit long-range antiferromagnetic order with the magnetite ferrimagnetic correlations confined to a single layer due to stacking faults of the spinel structure at the interfaces.¹ We are studying the field dependence of the interlayer coupling and magnetic structure in a series of $\text{Fe}_3\text{O}_4/\text{NiO}$ multilayers using neutron diffraction. Both NiO and Fe_3O_4 thin films were included in the measurements for comparison. In a single thick Fe_3O_4 film, intensity changes with magnetic field are consistent with the alignment of the net ferrimagnetic moment parallel to the applied field. In a single thick NiO film, we observe no intensity changes with magnetic field. For multilayers where the ratio of NiO to Fe_3O_4 is far from unity, the field dependence approximates that of the thick film of the majority constituent. However, for a Fe_3O_4 (68 Å)/NiO (34 Å) multilayer the NiO antiferromagnetic intensity decreases with increasing field, applied parallel to a [110] axis in the film plane. This indicates a domain repopulation in the NiO, concomitant with the magnetization of the magnetite, where the antiferromagnetic modulation direction prefers the [111] axes that are closest to the applied field direction. A broadening of the NiO peak shows that the repopulated domains are smaller. We are pursuing a complete measurement of the domain populations by measuring a series of NiO antiferromagnetic diffraction peaks. © 1996 American Institute of Physics. [S0021-8979(96)42308-0]

Exchange biasing has been studied for a series of [100] and [111] oriented, epitaxial Fe₃O₄/CoO bilayers grown by oxidic MBE. The low-temperature exchange biasing versus CoO layer thickness is compared to theoretical models for exchange biasing. We argue that the Malozemoff random field model does not apply to this system. The exchange biasing calculated according to the Meiklejohn-Bean model, assuming nearest-neighbor exchange coupling across a flat and magnetically uncompensated interface, differs for [100] oriented bilayers by a factor of ≈ 8 from the experimental value. © 1996 American Institute of Physics. I. INTRODUCTION

When a system, consisting of an antiferromagnet (AF) and a ferro- or ferrimagnet (F), is field cooled through the Néel temperature, T_N , of the AF, exchange anisotropy can shift the hysteresis loop along the field axis. This phenomenon is called exchange biasing.¹ Recently, the interest in this effect revived,²⁻⁵ due its application in magneto-resistive sensors.⁶ Still, the microscopic origin of this effect is poorly understood. In the extensively studied Ni-Fe/Fe-Mn system the magnitude of the loop shift or bias field, H_{eb} , is smaller by more than two orders of magnitude than calculated according to the original interpretation.^{4,6} In this interpretation the biasing is caused by a unidirectional anisotropy arising from nearest-neighbor exchange coupling across a perfectly flat interface which is magnetically uncompensated at the AF side.¹ If the ferromagnet is made single domain by a large applied field above T_N of the AF component, field cooling through T_N results in alignment of the AF interface spins to the aligned F interface spins. If the anisotropy energy of the AF is larger than the energy of this exchange coupling, reversing the F magnetization direction below T_N costs twice the energy associated with the exchange bonds across the interface. This requires an extra field, H_{eb} . Balancing the Zeeman energy with the exchange energy per F-AF bond, leads to:

$$H_{eb} = \frac{n2J_{ex}|S_F||S_{AF}|}{a^2\mu_0 M_F t_F} \quad (1)$$

with a the lattice parameter and n/a^2 the number of exchange coupled bonds across the AF-F interface per unit area, J_{ex} the exchange constant, S_i the spin of either F or AF, μ_0 the vacuum permeability, M_F the magnetization of the F layer and t_F the thickness of the F layer. Since Eq. (1) fails to describe the magnitude of H_{eb} in Ni-Fe/Fe-Mn, alternative models have been proposed, involving either planar domain walls⁷ or perpendicular domain walls due to interface roughness⁸ in the AF layer.

One of the problems in the study of exchange biasing is the lack of simple model systems. AF alloy systems such as FeMn have a complicated, noncollinear spin structure. Ox-

idic AF materials such as CoO have a simple collinear spin structure. Moreover, (bulk) properties of magnetic oxides are well documented.^{9,10} In addition, CoO has an experimentally convenient T_N of 291 K. Since molecular beam epitaxial (MBE) growth of magnetic oxidic multilayers of Fe₃O₄ and CoO or NiO has been demonstrated,¹¹ we decided to examine exchange biasing in MBE grown Fe₃O₄/CoO bilayers.

II. RESULTS AND DISCUSSION

Fe₃O₄/CoO bilayers were deposited on (0001) α -Al₂O₃ substrates¹² and on (100) SrTiO₃ substrates by oxidic MBE. In a limited oxygen partial pressure range $\approx 8.5 \times 10^{-5}$ mbar it is possible to grow both CoO and Fe₃O₄.¹³ RHEED and x-ray diffraction show that the deposition on SrTiO₃ results in epitaxial [100] oriented bilayers with a rocking curve of $\approx 1.3^\circ$ (FWHM). To study the exchange biasing, the bilayers were field cooled from 350 K in a 4400 kA/m field in a SQUID (Quantum Design MPMS5). After correction for the substrate's diamagnetic contribution, hysteresis loops as the one shown in Fig. 1 were obtained.

Two aspects of Fig. 1 are noteworthy. First of all, the M_S value is 473 ± 24 kA/m at 5 K, where the inaccuracy is mainly caused by the 2%-5% of precision with which the Fe₃O₄ thickness is determined by x-ray fluorescence (XRF). On average we find from all our bilayers $M_S = 476 \pm 49$ kA/m at 5 K for [100] oriented Fe₃O₄/CoO bilayers on SrTiO₃ with $t_{Fe_3O_4} = 120 \pm 10$ Å. This is below the bulk M_S of 510 kA/m of Fe₃O₄ at 5 K, but higher than $M_S \approx 370$ kA/m reported by other groups for [100] Fe₃O₄/CoO¹¹ and Fe₃O₄/NiO¹⁴ multilayers with comparable Fe₃O₄ thickness. Also in our [111] oriented bilayers, some of which were grown simultaneously with the [100] bilayers, M_S is lower.¹² A second interesting aspect of Fig. 1 is that we do observe a hysteresis loop shifted by the exchange bias field, H_{eb} , along the field axis, despite the fact that the (100) CoO plane forms a magnetically compensated plane, see Fig. 2(a). The most straightforward explanation of this observation is that the magnetic lattice parameter of the Fe₃O₄ to player is twice that of CoO. Hence exchange coupling across the interface occurs only to Co spins in one of the two magnetic sublattices, see Fig. 2(b).

In Fig. 3 we have plotted H_{eb} versus temperature, T , for

^{a)} Author for correspondence.

FIG. 1. Field cooled hysteresis loop at 5 K of an [100] oriented $\text{Fe}_3\text{O}_4/\text{CoO}$ bilayer with Fe_3O_4 thickness, $t_{\text{Fe}_3\text{O}_4}$ of 114 Å and CoO thickness, t_{CoO} of 30 Å. The loop is shifted or exchange biased by H_{eb} .

the same bilayer that gave the 5 K hysteresis loop of Fig. 1. The data are taken from the first loop after field cooling, because the training¹⁵ of the hysteresis loop was only 7% over the first ten hysteresis cycles at 5 K. This is to be compared to the $\approx 65\%$ training effect over the first nine hysteresis cycles in sputtered Ni-Fe/Fe-Mn bilayers at 10 K.¹⁵ H_{eb} is seen to depend linearly on T , consistent with our earlier data for [111] $\text{Fe}_3\text{O}_4/\text{CoO}$ bilayers¹² and those of other antiferromagnetic oxides.² In the bilayer in Fig. 3 the CoO thickness, t_{CoO} , is 27.8 ± 1.4 Å and the temperature at which H_{eb} vanishes, the blocking temperature, T_B , is 230 ± 10 K, well below T_N of bulk CoO of 291 K. As can be seen from Fig. 4, where T_B is plotted versus t_{CoO} for both [111] and [100] bilayers, the reduction of T_B below T_N of CoO appears to occur for $t_{\text{CoO}} < 50$ Å, independent of the bilayer orientation. Similar to the reduction of T_B for FeMn thinner than 100 Å

FIG. 2. (a) Schematic representation of the bulk spin structure of CoO. Oxygen atoms are represented by (●). The dotted lines connect the spins within identical (111) planes. For simplicity the Co spins are drawn parallel to the (111) plane. Note that the cube faces, the (100) planes are compensated, i.e., within them the net magnetization is zero. (b) Schematic illustration of the double magnetic lattice parameter of Fe_3O_4 with respect to CoO.

FIG. 3. The exchange bias field, H_{eb} , vs temperature, T , for the [100] $\text{Fe}_3\text{O}_4/\text{CoO}$ bilayer with $t_{\text{Fe}_3\text{O}_4} = 114$ Å and $t_{\text{CoO}} = 30$ Å. Note the linear dependence of H_{eb} on T . The biasing vanishes at the blocking temperature, $T_B = 230 \pm 10$ K. For $T \rightarrow 0$ H_{eb} extrapolates to $H_{eb}^{(0)}$.

in $\text{Ni}_{80}\text{Fe}_{20}/\text{FeMn}$ bilayers,¹⁶ the data in Fig. 3 can be described by a finite-size scaling formula:¹⁶

$$\frac{T_N - T_B(t_{AF})}{T_N} \propto t_{AF}^{-\delta}, \quad (2)$$

where t_{AF} is the antiferromagnetic layer thickness, with $\delta \approx 1.2$, which is comparable to $\delta = 1.6 \pm 0.3$ found for $\text{Ni}_{80}\text{Fe}_{20}/\text{FeMn}$ bilayers.¹⁶ This would imply that for $t_{\text{CoO}} < 50$ Å the magnetic correlation length becomes limited by the film thickness. We note that a recent study of the CoO thickness influence on T_B in $\text{NiO}/\text{CoO}/\text{Ni}_{80}\text{Fe}_{20}$ trilayers, suggests that for $t_{\text{CoO}} < 50$ Å the CoO T_B becomes sensitive to the NiO underlayer.² However, it remains to be proven whether the reduction of T_B below 50 Å is the result of an actual reduction of T_N in ultrathin CoO layers.

Since H_{eb} depends on T , discussions of biasing as well as comparisons to theoretical predictions of the magnitude of H_{eb} are best made with respect to the biasing data extrapolated to 0 K, $H_{eb}^{(0)}$.¹² Therefore, we have plotted $H_{eb}^{(0)}$ versus t_{CoO} in Fig. 5 for both [111] and [100] oriented $\text{Fe}_3\text{O}_4/\text{CoO}$ bilayers. The data for the [111] oriented bilayers are taken from Ref. 12. Figure 5 shows a very small t_{CoO} of ≈ 4 Å for the onset of biasing. This suggests that the CoO roughness is

FIG. 4. The blocking temperature, T_B vs t_{CoO} for [111] and [100] oriented $\text{Fe}_3\text{O}_4/\text{CoO}$ bilayers. For $t_{\text{CoO}} < 50$ Å T_B is lower than the CoO Néel temperature, $T_N = 291$ K.

FIG. 5. The exchange bias at 0 K, $H_{eb}^{(0)}$ vs t_{CoO} for a series of [111] and [100] oriented Fe_3O_4/CoO bilayers. The [100] oriented bilayers were grown on (100) $SrTiO_3$; the [111] oriented bilayers were grown on (0001) $\alpha-Al_2O_3$ substrates (Ref. 12). The Fe_3O_4 thickness is ≈ 120 Å. The onset of biasing occurs at $t_{CoO} \approx 4$ Å. $H_{eb}^{(0)}$ is maximum for t_{CoO} between 16–50 Å. The dashed curve is a guide to the eye through the [111] data.

≈ 4 Å and that it is possible to assess this roughness directly from exchange biasing data at low T .

Figure 5 shows that the dependence of $H_{eb}^{(0)}$ on t_{CoO} is roughly the same for the [100] and [111] orientation. Despite the qualitative similarity to the dependence predicted by Malozemoff's theory (viz., a regime where $H_{eb} \sim 1/t_{AF}$ followed by a regime, where H_{eb} is constant, see Fig. 5 of Ref. 8), we do not believe that this theory applies to the present system. First, the constant part is an artefact of the nonanalytic approximation to the random-field energy, which disappears when an analytic expression is used.¹⁷ After this correction the agreement with Fig. 5 is no longer obvious. Secondly, Malozemoff's model predicts a critical thickness above which biasing should disappear:⁸

$$t_{A,crit} = \frac{f_i \sqrt{A/K}}{4\sqrt{\pi}} \quad (3)$$

with f_i a parameter in the order of 1,⁸ A the exchange stiffness and K the uniaxial anisotropy constant of the AF. If $t_{A,crit}$ is calculated for the present case of an Fe_3O_4/CoO bilayer, one finds, using $K_{CoO} = 1.1 \times 10^7$ J/m³ (Ref. 18) that $t_{A,crit} \leq 2$ Å. Clearly, this is inconsistent with our experimental observations.

Finally, it is interesting to note that the Meiklejohn-Bean model works better in the present case than in metallic systems. $H_{eb}^{(0)}$ calculated from Eq. (1) by counting the number of Co-O-Fe superexchange bonds through a perfectly flat interface, using as estimate for $|J_{ex}| = 2.5 \cdot 10^{-22}$ J from similar bonds in spinels¹⁰ and $M_F \approx 476$ kA/m, yields $H_{eb}^{(0)} \approx 1500$ –3000 kA/m, depending on the interface model. The maximum value found for $t_{CoO} < 50$ Å in a [100] oriented bilayer is 294 kA/m, which is smaller by a factor of ≈ 8 . In Table I we have given the presently available low-temperature unidirectional anisotropy constants $K_{eb}^{(0)} = \mu_0 M_S H_{eb}^{(0)} t_F$ ^{12,19} with the ratio of the experimental and [from Eq. (1)] calculated $H_{eb}^{(0)}$. Table I shows that the [100] oriented Fe_3O_4/CoO bilayer system is closest to the straightforward ideas concerning exchange biasing proposed by Meiklejohn and Bean,¹ whereas $H_{eb}^{(0)}$ of MBE grown $Ni_{80}Fe_{20}/FeMn$ still differs considerably from this calculated value. This suggests that exchange biasing in metal alloy

TABLE I. The low-temperature unidirectional anisotropy constant $K_{eb}^{(0)} = \mu_0 M_S H_{eb}^{(0)} t_F$ and the ratio Δ of the biasing calculated from Eq. (1) and the experimentally found $H_{eb}^{(0)}$ for three MBE grown F/AF bilayers.

F/AF system	Interface	$K_{eb}^{(0)}$ (mJ/m ²)	Δ
Fe_3O_4/CoO	(100)	2.11	8
Fe_3O_4/CoO	(111)	1.43	35
$Ni_{80}Fe_{20}/FeMn$	(111)	0.22	73

systems is indeed more complex than in [100] oriented Fe_3O_4/CoO bilayers. The latter system may be a good model system to elucidate factors influencing exchange biasing, such as growth.

III. CONCLUSION

We have shown that oxidic [100] oriented Fe_3O_4/CoO bilayers grown on $SrTiO_3$ exhibit exchange biasing, despite the magnetically compensated (100) CoO interface. Exchange biasing is found up to 300 Å of CoO underlayer thickness, which is inconsistent with the predictions of Malozemoff's random field model, when applied to this system. The maximum value of exchange biasing extrapolated to 0 K, $H_{eb}^{(0)}$ is 294 kA/m, which is only a factor of ≈ 8 smaller than calculated on the basis of nearest-neighbor exchange across a perfectly flat interface. Compared to metal alloy systems such as $Ni_{80}Fe_{20}/FeMn$, [100] oriented Fe_3O_4/CoO bilayers may be a good model system to study exchange biasing.

Magnetic properties of exchange-coupled Fe/FeO bilayers

D. V. Dimitrov, A. S. Murthy and G. C. Hadjipanayis

Department of Physics and Astronomy, University of Delaware, Newark, Delaware 19716-2570

C. P. Swann

Bartol Research Institute, Newark, Delaware 19716

The magnetic, structural and microstructural properties of sputtered Fe thin films and Fe/Fe-O bilayers were studied as a function of the Fe layer thickness, the type of the Fe oxide and the substrate used. Two different ways to prepare the oxide layers were used; postdeposition oxidation and reactive sputtering. Postdeposition oxidation produced films with mixed Fe-oxides (FeO, Fe₃O₄, Fe₂O₃); however reactive sputtering led to bilayers with controlled stoichiometry, Fe/FeO, Fe/Fe₃O₄, and Fe/Fe₂O₃, respectively. The coercivity of both the Fe films and Fe/Fe-O bilayers, deposited on substrates with or without Cr buffer layer, was found to increase with decreasing Fe film thickness. The coercivity of the samples deposited on a Ag buffer layer was much lower and did not change substantially with the Fe film thickness. The presence of the Fe-oxide layer led to a large increase of coercivity. This is attributed to the higher anisotropy of the oxide and to exchange coupling of Fe-oxide with the softer Fe layer. © 1996 American Institute of Physics. [S0021-8979(96)17808-1]

INTRODUCTION

Iron oxide thin films have been studied extensively for the last few decades, mainly because of their application in magnetic recording media. Recently antiferromagnetic oxide films have been used to create exchange bias in spin valves.¹ However, it was found that the exchange coupling to the oxide layer deteriorates the properties of the soft magnetic layer.² Different kinds of deposition methods including magnetron dc and rf sputtering, molecular beam epitaxy and evaporation have been used³⁻⁷ to prepare films. The stoichiometry, magnetic and microstructural properties were found to depend substantially on the deposition parameters, substrates used, film thickness, and postdeposition annealing.³⁻⁷

In contrast, relatively little attention has been paid to iron-iron oxide systems.⁸⁻¹⁰ Schneider *et al.*⁸ found smooth hysteresis loops in evaporated Fe/Fe₂O₃/Fe sandwiches with coercivity of a few hundred Oe. They also observed columnar structure and perpendicular anisotropy. In contrast Ruf and Gambino⁹ observed very soft behavior with a coercivity ~5 Oe and planar anisotropy. Our previous studies¹⁰ on passivated fine Fe particles showed substantial increase in the coercivity due to the exchange coupling between the iron core and the iron oxide shell.

In this work we have extended our studies on small passivated Fe particles to Fe/Fe-O bilayers and we studied the effect of exchange coupling between the iron and iron oxide thin layers on the magnetic properties of the bilayers.

EXPERIMENT

Thin Fe films and Fe/Fe-O bilayers were prepared by dc magnetron sputtering in an atmosphere of 5 mTorr Ar on water cooled substrates. Carbon coated transmission electron microscopy (TEM) grids, aluminum foils, Kapton, glass slides, and carbon sheets were used as substrates. Two different methods were used to prepare the Fe/Fe-O bilayers; postdeposition oxidation in 500 mTorr of O₂ for 2 h or reactive sputtering in a mixture of Ar and O₂. Samples were

deposited either directly on substrates or on substrates with 30 nm Ag (Cr) buffer layers. All samples were covered with a 30 nm Ag layer for protection against further oxidation. The thickness of the Fe layer was varied between 5 and 40 nm, but the thickness of the reactively sputtered oxide was kept at 5 nm. The microstructure of the films was studied by TEM, using a Jeol JEM-2000 FX microscope. The thickness of the Fe films was determined by low angle x-ray diffractometry (XRD). The thickness of Fe oxide layers was determined by x-ray photoelectron spectroscopy for oxides made by postdeposition oxidation and Rutherford backscattering spectrometry (RBS) for oxides prepared by reactive sputtering. The stoichiometry of the oxide was determined by XRD and selected area diffraction (SAD). The magnetic properties were studied by a superconducting quantum interference device (SQUID) magnetometer in fields as high as 50 kOe and in the temperature range 10–300 K.

RESULTS AND DISCUSSION

All films were polycrystalline and quite uniform. The grains were small, typically 10 nm in size. Figure 1 shows a bright field micrograph of an oxidized 10 nm Fe film deposited on a Cr buffer layer. Unfortunately, the SAD patterns for Fe, Ag, and Cr are so close that they practically overlap, making it impossible to get separate dark field images of the buffer layer (Ag or Cr) and Fe film by itself.

Postdeposition oxidation produced an oxide layer, ~5 nm thick, consisting of a mixture of different oxides, FeO, Fe₃O₄, and Fe₂O₃. In contrast, by using reactive sputtering in a mixture of Ar and O₂, it was possible to make oxides with a determined stoichiometry. Figure 2 shows the XRD spectra for films sputtered with oxygen to Argon ratios 0.5%, 1%, and 4%. It is seen that under these conditions pure FeO, Fe₃O₄, and α -Fe₂O₃ are formed. RBS proved to be a very useful supplementary tool to XRD, allowing the relative amount of oxygen to iron to be estimated quite accurately. Figure 3 shows both a RBS and low angle XRD spectra of 15 nm Fe film deposited on glass. Analysis of the RBS spec-

FIG. 1. Bright field micrograph of 10 nm thick Fe/Fe-O bilayer prepared by postdeposition oxidation.

tra was done using the computer program RUMP.¹¹ From the theoretical fit of RBS spectrum one obtains the number of atoms per unit area in the film. Low angle XRD allows the thickness of the film to be calculated. For pure Fe films, combining the results from RBS with low angle XRD spectra we estimated that the density of Fe films was about 90% of the bulk. The result was very reproducible, with a dispersion <2%.

In order to understand the effect of exchange coupling between Fe and Fe-oxides on the magnetic properties of bilayers it was necessary to study the properties of pure Fe films first. The coercivity of the samples deposited directly on substrates, or on substrates with a Cr buffer layer, showed a very strong thickness dependence, in contrast to the

FIG. 3. RBS spectrum and low angle XRD insert for 15 nm Fe film on glass substrate.

samples deposited on a Ag buffer layer (Fig. 4). We believe that the reason for the different trend is the microstructure, which is different for the two kinds of films. It is well known that Cr layers are not smooth, but very rough with many voids. Because of this the Fe film resembles more of a particulate medium (isolated grains) than a continuous film. Another reason could be the formation of Fe-O in the interface between the underlayer and the film. This is also the case in films deposited directly on Al substrate. The saturation magnetization of the films was close to 1550 emu/cc, at 10 K, and did not change substantially with thickness for samples with a buffer layer. The result is similar to the one obtained from Kim and Oliveria.¹² The M_s value is lower than the bulk value of 1750 emu/cc, at 10 K, but is in excellent agreement with the estimated density (90% of bulk) of sputtered Fe films. The lack of any evidence for Fe oxides in XRD, SAD, and RBS spectra supports the idea that the lower value

FIG. 5. Effect of the oxide layer on the coercivity: comparison between pure Fe films and Fe/Fe-O bilayers prepared by postdeposition oxidation.

for the saturation magnetization is due to the lower density. For films deposited directly on Kapton and Al foil, a decrease of the saturation magnetization with decreasing thickness was found. A number of reasons could be responsible for this trend; these include partial oxidation because of the oxide layer on top of Al foil, iron atoms diffusing into Kapton (because it is very porous) or noncollinear spin structures on the surface of the film.

The oxide layer led to an increase in the coercivity for almost all the samples. The only exceptions were the thinnest samples deposited directly on Kapton. Figure 5 shows the effect for samples prepared by postdeposition oxidation. It is seen that the increase in the coercivity is most pronounced for the thinnest films. This result is analogous to the one observed in passivated Fe particles.⁹ It is attributed to the fact that for the thinnest samples, the relative number of Fe atoms exchange coupled to the Fe-oxide layer is the largest.

The trend seen in Fig. 5 is also representative of the samples prepared by reactive sputtering. The effect is strongest in the thinnest Fe/Fe₃O₄ bilayer deposited directly on Al foil, with an increase from 300 to 700 Oe at 10 K. For Fe/FeO and Fe/Fe₂O₃ bilayers the increase is smaller, from 300 to 515 Oe for Fe/FeO and to 490 Oe for Fe/Fe₂O₃. Shifted hysteresis loops for field cooled samples were observed in all bilayers, prepared by postdeposition oxidation and by reactive sputtering, confirming the presence of exchange coupling between Fe and Fe-O layers. Figure 6 shows the shifted loop for Fe/Fe₃O₄ bilayer with 10 nm Fe layer with a shift of 200 Oe. It is well known¹³ that the coercivity of soft materials can be increased by exchange coupling with a higher anisotropy material. FeO and α -Fe₂O₃ in bulk are known to be antiferromagnetic with low anisotropy. However, recent reports suggest a large surface anisotropy in Fe-oxides.¹⁴

FIG. 6. Shifted hysteresis loop observed in Fe/Fe₃O₄ bilayer.

Also our recent results on thin FeO films show a ferromagnetic behavior with significant magnetic hysteresis a coercivity >5 kOe at 10 K and saturation magnetization ~220 emu/cc. Both of these results indicate that the oxide layers may behave as strongly anisotropic, pinning the interface spins of the soft Fe layer and leading to high coercivity. We are studying these possibilities and the results will be reported soon.

In summary, the magnetic properties of Fe/Fe-O bilayers indicate the presence of a strong exchange coupling between the Fe film and Fe-O surface layer, resulting in a substantial increase in H_c. These results suggest a large anisotropy for the surface Fe-O oxides. The details of this interaction are presently being studied.

Effects of cooling field strength on exchange anisotropy at permalloy/CoO interfaces

Timothy J. Moran^{a)} and Ivan K. Schuller

Physics Department 0319, University of California—San Diego, La Jolla, California 92093

We have studied exchange anisotropy at ferromagnet/antiferromagnet (FM-AFM) interfaces as a function of cooling field in $\text{Ni}_{80}\text{Fe}_{20}$ (permalloy) films deposited on bulk single-crystal CoO substrates. Hysteresis loops measured after cooling through the antiferromagnetic ordering temperature in different magnetic fields show that the exchange bias has little dependence on cooling field. Large cooling fields produced hysteresis loops with larger remanent magnetization and larger coercivity. These trends can be explained using a model that assumes that the FM anisotropy axis directions can be influenced by the magnetic history of the AFM. Large cooling fields also led to larger CoO susceptibility, which implies rotation of the CoO spin axes. The simultaneous rotation of the FM anisotropy axes and the AFM spin axes suggests perpendicular coupling at the FM-AFM interface. © 1996 American Institute of Physics. [S0021-8979(96)17908-8]

Exchange anisotropy, which is magnetic anisotropy caused by the interaction of two neighboring magnetic materials, has been studied in many systems. These include permalloy/FeMn,¹ permalloy/TbCo,² and permalloy/ $\text{Co}_x\text{Ni}_{1-x}\text{O}$.³ This interest is partly due to the potential for application in the field of magnetoresistive sensors.⁴ Recent work has explored the interfacial structure dependence of exchange anisotropy.^{5,6} Here we report on a different aspect of the problem, studying how the magnitude of the cooling field affects the interface coupling. The results indicate cooling in large magnetic fields causes the FM anisotropy axes to be oriented parallel to the cooling field and the AFM spin axes to be perpendicular to the cooling field. Taken together, these results suggest a perpendicular coupling between the FM and AFM spins.⁷

The sample preparation is described elsewhere.⁵ Briefly, bulk single crystals of CoO with (111) or (100) orientation were given various surface treatments such as sanding, polishing, heating, and ion bombardment. $\text{Ni}_{80}\text{Fe}_{20}$ (permalloy) films, 100 or 200 Å thick, were deposited at room temperature using a Riber MBE system with a typical pressure of better than 5×10^{-9} Torr during deposition.

The magnetic measurements were performed with a Quantum Design SQUID magnetometer, making use of the magnet reset option to reduce the magnetic field offset in the sample space. The field was applied in the plane of the film. Before each measurement the samples were heated to 400 K, which is above the ordering temperature of CoO ($T_N=291$ K), but low enough that the heating is unlikely to cause large structural changes.⁸ The samples were then cooled to 50 K in a magnetic field, H_{cooling} . Hysteresis loops were then measured over the range (-1500 Oe, 1500 Oe). For each hysteresis loop a large linear background due to the CoO susceptibility $\chi(\text{AFM})$ had to be subtracted.

Figure 1 shows two hysteresis loops for a permalloy/CoO sample for two different cooling fields. Both loops exhibit a shift toward the negative field direction. This shift, known as the exchange bias (H_E), is defined as the field

halfway between the two field axis intercepts. The coercivity (H_C) is defined as the average magnitude of the two field axis intercepts. The remanence (m_r) represents the average of the two zero field moment values. The reduced remanence (m_r/m_s) is calculated by dividing average zero field moment by the saturation moment, where the saturation moment was determined by averaging over several loops. Understanding the exchange bias magnitude has been the main goal of previous exchange anisotropy studies. However, this report will focus on the other effects visible in Fig. 1, which are that the $H_{\text{cooling}}=70$ kOe loop has larger remanence and larger coercivity.

Figure 2 shows the exchange bias, coercivity, reduced remanence, and CoO susceptibility $\chi(\text{AFM})$, for two different samples as a function of the magnitude of the cooling field. We will discuss the FM behavior first and then the AFM behavior. The exchange bias changed very little (<5 Oe) for different cooling fields for all samples measured. For some samples the exchange bias decreased for larger cooling fields while in others it increased or remained constant. The remanence increased with larger cooling fields for seven out of eight samples measured. In most cases, the coercivity also

FIG. 2. (a) Reduced remanence (m_r/m_s), (b) coercivity (H_C), (c) exchange bias (H_E), and (d) CoO susceptibility $\chi(\text{AFM})$ measured at $T=50$ K as a function of cooling field magnitude (H_{cooling}) for two different samples: (circles) 200 Å permalloy/CoO(111), (triangles) 200 Å permalloy/CoO(100). The lines are guides to the eye.

increased for larger cooling fields, although this data contained some scatter. These results were reversible with cooling field; in other words the values in Fig. 2 did not vary depending on the order of the measurements. The same trends were observed for samples cooled in positive or negative magnetic fields.

The trends toward higher coercivity and remanence are similar to the behavior expected for a ferromagnet having a uniaxial anisotropy axis which changes its direction relative to the applied field. For a single domain FM with uniaxial anisotropy, hysteresis loops will have higher remanence and coercivity if the anisotropy axis is more parallel to the applied field.⁹ Therefore the variation in magnetic properties with different cooling fields is possibly due to changes in direction of the anisotropy axes governing the FM behavior.

For this model [Fig. 3(a)], the FM has uniaxial anisotropy but is divided into different regions, each having different directions for the anisotropy axis. The low cooling field state has a wide distribution of anisotropy axes, while for the high cooling field state the anisotropy axes are more parallel to the field direction. To test this model theoretical hysteresis curves were calculated and compared to the data. For the calculation the anisotropy axes were assumed to follow a Gaussian distribution $W(\theta_K) \propto \exp[-(\theta_K)^2/2(\theta_{\text{fan}})^2]$, where

FIG. 3. Illustration of model described in the text, showing a top view of FM regions having various anisotropy axes. Large cooling fields produce FM anisotropy axes which are parallel to the cooling field, and AFM spin axes which are perpendicular to the cooling field.

$W(\theta_K)$ is the weighting function, θ_K is the angle between the anisotropy axis and the field axis, and θ_{fan} is the angular spread of the axes.

Figure 1 shows calculated hysteresis curves with exchange bias, saturation moment, and FM anisotropy set at $H_E=24$ Oe, $m_s=0.00042$ emu, and $K(\text{FM})=110\,000$ ergs/cc, respectively to match the data. The only difference between the calculated curves is the angular spread of the axes, θ_{fan} , which changes from 10° to 35° . The agreement with the data implies that the physical properties of the sample are not changing, only the spread in the anisotropy axes.

The most likely source of this change is the magnetic structure in the AFM, which has been changed by heating the sample above the AFM ordering temperature and cooling in a different magnetic field. It is important to note that for these samples the FM coercivity is strongly influenced by interactions with the AFM.⁵ The low-temperature coercivity, typically 200 Oe, is much larger than the room temperature coercivity, typically 30 Oe, with a sharp rise near the ordering temperature of the CoO, $T_N=291$ K. A 200 Å permalloy film deposited under the same conditions onto silicon had coercivities that were smaller (<5 Oe) and did not change with temperature (up to 400 K) or cooling field (up to 7 T). Therefore the mechanism driving the cooling field effects in Figs. 1 and 2 are very likely related to changes in the AFM.

Fortunately the AFM susceptibility data in Fig. 2 provides information about the spin structure in the AFM. Figure 2(d) shows that the low field CoO susceptibility, measured at $T=50$ K with $|H|<1.5$ kOe, increases for larger cooling fields. This change in the susceptibility indicates that the spin axes of the CoO are more perpendicular to the field if the AFM has been exposed to large magnetic fields. (See Fig. 3) This is because the AFM susceptibility is largest when the spin axis is perpendicular to the applied field. Rotation of AFM spin axes toward directions perpendicular to large magnetic fields has been observed previously in MnO ¹⁰ and MnF_2 .¹¹

To recap, the change in FM remanence and coercivity

implies that the FM anisotropy axes are more parallel to the applied field after cooling in large magnetic fields [Fig. 3(a)]. The change in AFM susceptibility implies that the AFM spin axes are more perpendicular to the applied field after cooling in large magnetic fields [Fig. 3(b)]. If one assumes that the FM spins have an energy advantage to align perpendicular to the AFM spins, the FM anisotropy axis rotation can be easily explained. Under this assumption of perpendicular coupling, the large cooling field causes the AFM spin rotation, which then causes the FM anisotropy axis rotation. If perpendicular coupling does exist, it may be related to the perpendicular coupling that has been observed recently between ferromagnetic Fe layers separated by thin Cr layers.⁷ Recent work in our laboratory indicates that perpendicular coupling also occurs in the ferromagnet–antiferromagnet system Fe/FeF₂.¹² Other workers have discussed possible perpendicular coupling at permalloy/FeMn interfaces.¹³

In conclusion, we have discovered changes in the behavior of an FM layer adjacent to an AFM, which are due to cooling through T_N in large magnetic fields. The data can be explained by a model where different FM regions have different anisotropy axes, and the distribution of these axes is altered by cooling through different magnetic fields. Susceptibility data from the AFM indicate that the AFM spin axes are also influenced by large cooling fields. Together these two trends suggest that the FM spins and AFM spins may have perpendicular coupling.

The role of interface crystalline and magnetic structure in exchange anisotropy (abstract)

J. Nogués, D. Lederman,^{a)} and Ivan K. Schuller

Department of Physics, University of California—San Diego, La Jolla, California 92093-0319

K. V. Rao

Royal Institute of Technology, Stockholm, Sweden

Large exchange bias effects were measured in antiferromagnetic FeF_2 -ferromagnetic Fe bilayers. The interface spin structure and roughness was controlled by using different substrates and growth temperatures. The samples were characterized *ex situ* using low and high angle x-ray diffraction, in-plane x-ray diffraction, and atomic force microscopy. We discovered that the exchange bias is largest in the (110) FeF_2 spin-compensated surface films, in contradiction with simple models that predict a low exchange anisotropy for spin-compensated surfaces. For these samples, the exchange anisotropy decreases as the interface roughness increases. © 1996 American Institute of Physics. [S0021-8979(96)42408-8]

Topological coupling in magnetic multilayer films

J. Zhang and R. M. White

Data Storage Systems Center, Department of Electrical and Computer Engineering, Carnegie Mellon University, Pittsburgh, Pennsylvania 15213

The role of topological coupling, the magnetostatic coupling associated with interfacial roughness in magnetic sandwich/multilayer structures, was studied both analytically and experimentally. We report the first controlled measurements of such topological coupling. A coupling field of the order of 10 Oe between magnetic layers was observed in Co/Cu/Co sandwich structures fabricated with an artificially controlled in-phase roughness of variable amplitude with a fixed period of $3.5\text{ }\mu\text{m}$. The coupling field was compared with the value predicted by a first-order approximation model and correlated with the geometry of the structure. Scale invariance of the coupling field allows the results to be extended to ultrathin giant magnetoresistance/spin valve structures. © 1996 American Institute of Physics. [S0021-8979(96)18008-2]

I. INTRODUCTION

Coupling between magnetic layers separated by non-magnetic interlayers has attracted enormous interest and has been studied with accelerated vigor since the discovery of the giant magnetoresistance (GMR) effect.¹ This coupling may align the magnetization in adjacent magnetic layers parallel or antiparallel. Various mechanisms have been proposed to explain the coupling. In the case where the spacer layer is thin and conducting, exchange-like coupling can occur through conduction electrons. The sign of this coupling is predicted to oscillate with the interlayer thickness and this has been observed in various systems.² Since this coupling has an exchange origin, it is usually strong. Another important mechanism, which is of magnetostatic origin and was first suggested by Néel,³ is the magnetostatic coupling caused by magnetic free poles induced by interfacial roughness. The roughness at the interfaces is generally correlated in the case of as-deposited multilayers due to the propagation of the roughness profile from layer to layer. This kind of coupling exists in structures with both thick and thin interlayers, as long as roughness exists, and is generally small. However, its importance can not be overestimated, especially in weakly coupled low field GMR/spin valve materials,^{4,5} which are critical for device applications such as high density magnetic recording read heads and magnetoresistive random access memories,⁴ etc.

A lot of work has been done for exchange-based coupling. However, not as much was done for magnetostatic coupling, especially topological coupling. The reasons are twofold. First, the roughness in ultrathin multilayers is uncontrolled. Second, it is difficult to distinguish magnetostatic coupling from exchange coupling when the spacer thickness is on a nanometer scale. Although results on topological coupling have been reported,⁶ no study has ever been done with controlled roughness. The purpose of this study is not only to demonstrate the existence of topological coupling, but also to study it in a controlled way, and to consider the implications for ultrathin GMR/spin valve structures.

II. THEORETICAL ANALYSIS

The origin of the topological coupling can be seen from Fig. 1(a). Assuming a uniform magnetization in the films,

magnetic free poles are induced at the interfaces due to interfacial roughness. When the roughness at adjacent interfaces is in-phase, which is generally the case for as-deposited films, the magnetizations of the two magnetic layers tend to align with each other to achieve a low energy state, giving a ferromagnetic coupling.

The first calculation of topological coupling was carried out by Néel.³ His analytical analysis assumed semi-infinite magnetic layers with a correlated sinusoidal interface roughness and a distribution of induced surface magnetic charge distribution projected onto a smooth surface. A closed form expression for surface interaction energy was obtained. Using a numerical approach, we have extended Néel's model to consider the roughness with an arbitrary phase difference (i.e., not necessarily correlated) and a finite magnetic layer thickness. The geometry used in the model is shown in Fig. 1(a). The sinusoidal roughness has a peak-peak amplitude of h , period p , magnetic layer thickness is t with magnetization M , and spacer thickness is d . As a first-order approximation, an in-plane uniform magnetization was assumed. This assumption holds as long as the magnetic layer has an in-plane uniaxial anisotropy and the roughness amplitude h is much smaller than the period p . Both top and bottom interfaces of two magnetic layers (A, B, A', B') were included in the interaction energy calculation due to the finite thickness of the

FIG. 1. (a) In-phase sinusoidal interface roughness in multilayers. (b) In-phase step interface roughness in multilayers. The structure shown in (b) was actually fabricated.

FIG. 2. Ferromagnetic coupling field due to two inner interfaces $A-B$ only for in-phase sinusoidal and step roughness with dimensions used in experiments ($p=3.5 \mu\text{m}$, $h=200-400 \text{ Å}$, $d=1000-5000 \text{ Å}$, $t=1400 \text{ Å}$, magnetization of Co is 1400 emu/cm^3).

magnetic layers. It was found that the surface interaction energy was proportional to $\cos \varphi$, where φ is the roughness phase. For the special case of $\varphi=0$ (in-phase roughness), a negative interaction exists for magnetizations shown in Fig. 1(a) and indicates a ferromagnetic coupling, while for $\varphi=\pi$ (out-of-phase roughness), an antiferromagnetic coupling exists. We will concentrate on the in-phase case in this paper. The coupling field can be obtained by $H_{\text{int}}=E_{\text{int}}/Mt$, where t is the thickness of the magnetic layer. It can be shown that the coupling field is scale invariant; i.e., the coupling field is independent of the actual size of the structure as long as the aspect ratio remains the same. This prompted us to study topological coupling by using structures on a larger scale.

The interaction energy for an arbitrary roughness profile can be obtained by a Fourier decomposition. One simple and interesting case of the in-phase roughness is the step roughness as shown in Fig. 1(b), since it can be easily fabricated and controlled experimentally. The same geometrical parameters, h , p , t and d were used as in the sinusoidal case. For clarity, the coupling field due to two inner interfaces ($A-B$) only is plotted in Fig. 2 for both sinusoidal and step roughness with geometries used in Sec. III. (We assume Co is used for the magnetic layer). It is clear that the coupling field for the step roughness is larger than that of the sine roughness, and it decreases more quickly as interlayer thickness increases. The total surface interaction energy is the algebraic sum of the interaction energy for all interfaces, namely, $A-B$, $A'-B'$, $A-B'$, and $A'-B$. The first two contribute to a ferromagnetic coupling, the latter two give rise to a smaller antiferromagnetic component. Thus we expect structures with an in-phase step roughness to be dominated by ferromagnetic coupling. The total coupling field for Co/spacer/Co structures with the step roughness as shown in Fig. 1(b) is plotted in Figs. 3 and 4 for variable roughness amplitude h and interlayer thickness d . Markers are experimental data, as will be discussed in Sec. III. It can be seen that the coupling field given by the model increases as d decreases and h increases. The coupling field is also expected to be proportional to the magnetization M .

FIG. 3. Model predicted H_{int} and measured $\Delta H_c/p$ in Co/Cu/Co sandwich structures with the step roughness for variable roughness amplitudes $h=400-800 \text{ Å}$.

If the magnetic layers have square hysteresis loops ($S=1$) and the same coercivity, the ferromagnetic coupling will appear as an increase of the coercivity of the bilayers H_{c2} compared to that of a single layer H_{c1} . The coupling field is then given by $H_{\text{int}}=H_{c2}-H_{c1}$.

III. EXPERIMENT

Co/Cu/Co sandwich structures with correlated artificial step roughness were fabricated on Si substrates. The material and the dimension of the structure were chosen to make the coupling observable and films with good magnetic properties possible to fabricate. The artificial surface roughness was created by an array of nonmagnetic Cu strips fabricated using a standard lift-off process. The amplitude (varied from 400 Å to 800 Å) and the period (fixed at $3.5 \mu\text{m}$) of the roughness were individually controlled by the thickness and the width of the metallic strips, respectively. An atomic force microscope (AFM) image of the Si substrate with such step roughness is shown in Fig. 5. The fine grooves were determined to be the original roughness on the substrate and its amplitude is less than 50 Å (pk-pk), which is small compared to the artificial roughness. A 1500 Å Cu seed layer was de-

FIG. 4. Model predicted H_{int} and measured $\Delta H_c/p$ for variable interlayer thickness $d=1000-1500 \text{ Å}$.

FIG. 5. AFM image of artificially created step roughness. The z axis is highly exaggerated to show details ($h=400$ Å, $p=3.5$ μm).

posited, followed by a Co/Cu/Co sandwich structure deposition in a Perkin-Elmer 2400-8L sputtering system without breaking the vacuum. The base pressure was below 2×10^{-7} Torr. A magnetic field perpendicular to the stripes was used to create an in-plane uniaxial anisotropy. The Cu seed layer was used to assure that two Co layers were symmetric and have the same magnetic properties. The Cu interlayer thickness ranges from 1000 Å to 1500 Å, which is thick enough so that exchange coupling is negligible. The artificial roughness on the substrate was found to propagate after the deposition, as expected.

The sample thus made was then cut in half. One half was sputter etched to peel off the top magnetic layer. The other half was also mounted in the etching chamber, but masked, to avoid any possible thermal effect on the film magnetic properties. The hysteresis loop was measured on a B - H loop, and a coercivity increase of the order of 10 Oe for bilayer structures was observed compared with single layers, as shown in Fig. 6, indicating a ferromagnetic coupling. The increase of the apparent coercivity $\Delta H_c = H_{c2} - H_{c1}$ is defined as the measured coupling field.

Another set of films was made using the same procedure but on flat substrates. No coupling was observed. This confirmed that exchange coupling does not exist, and the coupling observed in structures with roughness was totally due to magnetostatic coupling.

FIG. 6. Typical B - H loops for bilayers and single layers deposited on substrates with step artificial roughness.

IV. RESULTS AND CONCLUSION

As shown in part II, when squareness $S=1$, the apparent coercivity of a sandwich increases by H_{int} . However, as can be seen in Fig. 6, the loops were not perfectly square. Before correlating the measured coupling field, the nonsquare shape of hysteresis loops must be taken into account. When $S \neq 1$, the free magnetic poles available in bilayers near H_{c1} (coercivity of single layer) are less than that at saturation. Thus we define $p = M_2(H_{c1})/M_{s2}$ as a parameter that characterizes this reduction, where $M_2(H_{c1})$ is the magnetization of bilayers at the coercivity of single layers, and M_{s2} is the saturation magnetization of bilayers. Assuming that two magnetic layers switch simultaneously and uniformly, we expect that the measured coupling field ΔH_c is smaller than in films with $S=1$, given approximately by pH_{int} . This means $\Delta H_c/p$ should correlate to the modeled H_{int} . The measured $\Delta H_c/p$ is plotted for variable roughness amplitude h and interlayer thickness d in Figs. 3 and 4, respectively. It can be seen for small roughness amplitude, $\Delta H_c/p$ is close to the coupling field predicted by the model. However, when the roughness amplitude increases, the demagnetizing field associated with the roughness increases and results in domain formation, especially near the edges of the steps, which invalidates the assumption of uniform switching and reduces the coupling field. The dependence of the coupling field on interlayer thickness is in much better agreement with the model. The discrepancy between the measured and predicted values is due to approximations in the model, measurement error and film deposition nonuniformity.

Scale invariance allows us to apply the above results to ultrathin GMR/spin valve structures although the exchange coupling might be important in this range. Topological coupling could be used to create the coupling in GMR/spin valve films,^{5,7} in which antiparallel alignment of magnetic moments is essential. For device applications, a low saturation field, i.e., very weak coupling, is required. The existence of ferromagnetic topological coupling could be used to partially cancel an antiferromagnetic exchange coupling and thereby reduce the net coupling.⁵ On the other hand, if magnetostatic coupling is dominant, it could be reduced by obtaining uncorrelated rough interfaces using thermal annealing.⁷

The development of surface roughness in Co/Cu systems was investigated through the use of *in situ* scanning tunneling microscopy. Multilayers and single layers of cobalt and copper were sequentially grown on a Cu(100) substrate. We show that the growth mode of cobalt on copper is quite different from that of copper on cobalt. We characterize these differences by looking at the lateral variations and obtaining a mean measure of island length. The cobalt tends to nucleate in small (<5 nm) islands. An overlayer of copper broadens this length scale while maintaining approximately the same peak-to-peak roughness of 5 monolayers. These growth mechanisms are shown to affect the way in which roughness propagates through multilayers. The impact of deposition temperature is also examined and seen to alter the degree of roughness in these samples. We conclude by discussing the implications for the magnetoresistance of these structures. © 1996 American Institute of Physics. [S0021-8979(96)22608-3]

I. INTRODUCTION

The effect known as giant magnetoresistance (GMR) has generated much interest in magnetic multilayered structures.¹⁻³ At the heart of the phenomenon is the spin dependent scattering of carriers by thin magnetic layers separated by nonferromagnetic spacers. The Co/Cu system is worth noting because of its large value of magnetoresistance in both multilayer and spin valve systems. Since the effect depends strongly on the oscillatory antiferromagnetic coupling and surface roughness, it is important to obtain a clear understanding of the growth mechanisms of the individual layers. We have examined the surface evolution of a number of Co/Cu films through *in situ* scanning tunneling microscopy (STM). These films were grown with the goal of ascertaining the impact that each material has on the development of roughness in multilayers.

II. EXPERIMENT

The films were grown via ion-beam sputtering (IBS) at a pressure of 2.5×10^{-4} Torr of argon. Background pressures were low ($< 5 \times 10^{-10}$ T) throughout the study. The deposition rate was 0.1 Å/s for cobalt and 0.2 Å/s for copper. Rate measurements and thickness determinations were performed using an *in situ* quartz crystal. The substrate used was a Cu(100) crystal that was sputter etched and annealed prior to each deposition. Each sample was measured with an *in situ* STM⁴ at 1–4 nA of tunneling current. X-ray photoemission spectroscopy (XPS) measurements indicated that contaminant levels were negligible. All samples were, unless otherwise noted, grown at room temperature at a beam voltage of 1000 V.

In this surface study, we needed a useful way to characterize the in-plane, lateral variations of the films we grew. The horizontal dimensions of layers at the same atomic height varied greatly depending on the order in which the

various materials were deposited. Since auto-correlation and Fourier techniques proved too sensitive to substrate steps, we instead used mean island length as an indicator of lateral roughness.

Low-energy electron diffraction (LEED) patterns revealed that the samples were epitaxial with evidence of twinning. Similar observations have been made⁵ in related systems where twinning was found to have an effect on the coupling between ferromagnetic Co layers.

III. RESULTS AND DISCUSSION

A. The growth modes of cobalt and copper

The way in which cobalt/copper layers form during dc magnetron sputtering has been described elsewhere.⁶ In general, copper is thought to act as a “smoothing agent” when grown on cobalt. This behavior may help explain the variation in the strength and type of coupling with the number of layers in multilayered films. We found that the way in which copper acts to reduce roughness in IBS-grown films on single crystals is confined primarily to the lateral dimension. The peak-to-peak roughness proved fairly insensitive to the amount of copper grown on cobalt. Instead, the in-plane characteristic lengths varied greatly with the amount of copper deposited. The STM indicated that this is the most distinguishing form of roughness in these films.

First we describe the way in which cobalt grows on copper as illustrated in Fig. 1 (all figures are 600 Å wide). This sequence initiates much of the roughness seen in these films. The initial layer of cobalt is seen to grow via island nucleation with the second layer beginning before the first is finished. Growth beyond the first several layers is essentially cobalt on cobalt. The cobalt progresses via this mechanism to develop a rough surface on the copper substrate. Small, numerous islands indicate that cobalt has a low mobility on copper. Peak-to-peak roughness is 4–5 monolayers at 21 Å.

Note the small lateral lengths in these images. It is quite clear that the growth of the cobalt is not layer by layer and

FIG. 1. Roughness development in films of the form: $\text{Cu}(100)/\text{Co}$ (n Å) for (a) $n=1$, (b) $n=3$, (c) $n=10$, and (d) $n=21$. Full width is 600 Å.

that the horizontal dimensions of contiguous, same-height areas is small. A typical characteristic length is 40 Å after 21 Å of vertical growth. In this sense, cobalt on copper demonstrates a high lateral roughness.

The growth of copper on cobalt proceeds in a very different fashion. As shown in Fig. 2, even a few angstroms of copper is sufficient to show its larger surface mobility. The copper acts to smooth the surface in the lateral dimension. Peak-to-peak roughness remains fairly constant throughout

FIG. 2. Roughness development in films of the form: $\text{Cu}(100)/\text{Co}(21 \text{ Å})/\text{Cu}(n \text{ Å})$ for (a) $n=1$, (b) $n=5$, (c) $n=21$, and (d) $n=40$. Full width is 600 Å.

FIG. 3. Copper (top layer) decreases the lateral roughness of cobalt (bottom layer) due to its higher mobility.

various thicknesses, however. A typical characteristic length for these films is 150 Å after 21 Å of vertical growth.

If we contrast Figs. 1 and 2 we see what the effects of copper are on these depositions. The peak-to-peak roughness remains largely unaffected even with increasing thicknesses of copper, while the lateral roughness increases dramatically. These concepts are illustrated in Fig. 3 where it is shown how two layers with the same peak-to-peak roughness can exhibit marked differences in the lateral direction.

B. Bilayer progression

We next investigated roughness at the bilayer level. These structures are of interest in relation to the GMR effect. The way in which the atomic level roughness develops through the first bilayer is important for both spin valves and multilayers. We used our results for the effects on roughness from copper and cobalt on these thicker structures. Several samples of the form $\text{Cu}(100)/[\text{Co}(21 \text{ Å})/\text{Cu}(21 \text{ Å})]_n$ were grown and the results are shown in Fig. 4.

For clarity, we used the smoothing effects of copper to examine the roughness for 1, 2, and 5 bilayers by always looking at the top copper layer. The roughness is fairly evi-

FIG. 4. Bilayer roughness in films of the form: $\text{Cu}(100)/[\text{Co}(21 \text{ Å})/\text{Cu}(21 \text{ Å})]_n$ for (a) $n=1$, (b) $n=2$, (c) $n=5$. Full width is 600 Å.

FIG. 5. (a) Cu(100)/Co(21 Å) grown at $T = 150$ °C. Full width is 600 Å.

dent with up to 6 or 7 monolayers of roughness visible in a multilayer composed of 5 bilayers. There is not a great deal of change with increasing number of bilayers. Instead, the degree of roughness seems fairly well set with the completion of the first or second bilayer.

The implications for GMR in these films are not good because of the high peak-to-peak roughness. To account for any uncontrolled variability in deposition rate, we grew multilayered wedges where the copper thickness was varied by as much as 15 Å. Magnetoresistive measurements indicated no (<1%) change in resistance over the entire sample for fields up to several thousand oersted. The hysteresis loops of the film were also measured using the magneto-optic Kerr effect (MOKE) and no antiferromagnetic coupling was present.

C. Temperature effects

It is known⁷ that cobalt and copper do not interdiffuse more than a few monolayers at room temperature. To illustrate the effect of elevated temperatures on cobalt mobility and consequently roughness, 21 Å of cobalt was grown at 150 °C. It is immediately apparent (see Fig. 5) that the lateral scale of the islands is much larger than for room temperature. Comparing Fig. 5 with Fig. 1(d) suggests that the difference in temperature seems to have given the cobalt atoms a much greater mobility that allowed for more layered growth. Note that the peak-to-peak roughness is still similar.

A bilayer formed at this temperature shows [see Fig. 6(b)] a great deal more smoothness in the lateral direction than an identical structure grown at room temperature [see Fig. 6(a)]. The enhanced copper mobility has clearly resulted in a film whose lateral variation is quite reduced in comparison to a film grown at room temperature. Even more striking is the same film grown at -50 °C [see Fig. 6(c)]. At this low temperature, the characteristic lateral lengths have been clearly reduced. This occurred despite the presence of 21 Å of copper which, as we have seen, ordinarily provides for longer lengths.

IV. CONCLUSIONS

With the STM we see that the evolution of roughness in IBS-grown Co/Cu films depends strongly on the growth

FIG. 6. Cu(100)/Co(21 Å)/Cu(21 Å) grown at (a) room temperature, (b) at $T = 150$ °C and (c) at $T = -50$ °C. Full width is 600 Å.

mechanisms of each component. Although usually viewed in peak-to-peak terms, roughness throughout this study varied more in the horizontal length scales. Cobalt tends to grow in small islands that produce rough coverage, meaning that the length scales that are characteristic in these surfaces are small (<50 Å). Due to its larger mobility, copper extends the lateral dimensions of the surface without strongly influencing peak-to-peak roughness.

The cumulative effects of these growth modes on bilayer progression are that the degree of roughness for Cu(100) substrates is mostly set by the first two bilayers and increases only slightly beyond that. This effect is consistent with the absence of GMR in these structures.

Finally, the mobilities of copper and cobalt can be altered by changing the growth temperature. This results in enhanced characteristic lengths at higher temperatures and diminished ones for lower temperatures.

⁵⁹Co nuclear magnetic resonance studies of the effect of annealing molecular beam epitaxy grown Co/Cu(111) multilayers

T. Thomson and P. C. Riedi

B. J. Hickey

Department of Physics, University of Leeds, Leeds, United Kingdom

⁵⁹Co NMR, magnetotransport and grazing incidence x-ray scattering studies have been undertaken on a series of Co/Cu(111) multilayers, grown by molecular beam epitaxy (MBE), and subsequently annealed. Magnetotransport measurements showed that the magnetoresistance ($\Delta\rho/\rho$) decreased only slightly as the annealing temperature was increased, but both the resistivity ρ and the change in resistivity $\Delta\rho$ doubled. NMR measurements showed that the strain in the interior of the Co layers relaxed slightly as a result of annealing while the strain at the interfaces remained constant. A small increase in the ratio of the area under the main NMR line to the area under the interface line, together with a reduction of interface line area, suggests a slight deterioration in the quality of the interfaces as a result of annealing. These observations are consistent with the model that MBE grown multilayers require good quality interfaces for large magnetoresistance (MR). Data from x-ray measurements showed that the increase in resistivity could be explained as a result of alloying between the top Cu layer of the multilayer and the Au capping layer. © 1996 American Institute of Physics. [S0021-8979(96)18108-9]

I. INTRODUCTION

Co/Cu(111) multilayer films exhibiting giant magnetoresistance (GMR) are still currently receiving much attention¹⁻³ both at a fundamental level and for applications in magnetic recording systems. In this work we report on the effect of thermal annealing a series of molecular beam epitaxy (MBE) grown Co/Cu(111) multilayer films using the complementary techniques of ⁵⁹Co NMR and x-ray scattering, together with magnetotransport measurements. This article is mainly concerned with the investigation of these materials using spin echo NMR spectroscopy and correlating the results obtained with magnetotransport and x-ray scattering measurements. A more comprehensive discussion of the x-ray results and magnetotransport measurements may be found in Ref. 4.

NMR is essentially a microscopic probe of the local atomic environments. When excited by the applied radio frequency field the nucleus precesses in an effective magnetic field (hyperfine field) determined by the atomic environment. The atomic environment can be modified by the inclusion of different atoms in the vicinity of the atom containing the probe nucleus. This can occur as a result of alloying and at interfacial regions in multilayer materials. Hence at ideally flat, planar interfaces in the fcc Co/Cu(111) system one would expect an atomic environment of 9×Co nearest neighbors (NN) and 3×Cu NN.^{6,7} Structural imperfections such as grain boundaries can also lead to a change in the effective magnetic field at the nucleus. If the material under investigation is strained, then the hyperfine field changes as a result of the change in interatomic distance. In these MBE grown films strain results from the lattice mismatch (Co=3.54 Å, Cu=3.61 Å) between Co and Cu.

II. EXPERIMENT

A single multilayer film was grown at the MBE facility in Leeds. A base pressure of 3×10^{-11} mbar was obtained in

the MBE chamber, and a high degree of uniformity across the sample was ensured by rotating the sample at 1 Hz throughout the grown process. The film was grown on a polished single crystal sapphire substrate of dimensions 12×10×1 mm oriented normal to the (1120) direction. A buffer layer, consisting of Nb 60 Å deposited at 950 °C followed by Cu 30 Å, was grown on the sapphire prior to the multilayer. The multilayer consisted of Co 11.5 Å/Cu 7 Å_{×20}, a Au cap of 38 Å was deposited to inhibit oxidation.

The final film was cut into 8×2 mm sections using a diamond saw. The resulting identical samples were annealed in a stream of oxygen-free nitrogen for 45 min at 200, 260, 290, and 320 °C. A fifth sample was left unannealed as a control.

The ⁵⁹Co NMR spectra were measured in a phase detected, swept frequency spin echo spectrometer^{8,9} with the samples in a tuned circuit. During the course of the experiments only the tuning and matching of the sample coil were changed, so any errors due to mismatches and standing waves in the instrument are identical in all the spectra measured. Corrections for ω^2 and variations in the spin-spin relaxation time (T^2) with frequency were made in the usual way.⁶ All spectra were measured at 4.2 K.

Magnetoresistance (MR) measurements were carried out using a standard four probe method with collinear, pressure type electrical contacts. All MR measurements were performed at 4.2 K in applied fields up to 4 T using a geometry with the current and applied field parallel, and in the plane of the film. The resistivities ρ were obtained assuming a uniform current throughout the cross section of the films.

III. RESULTS AND DISCUSSION

The results obtained from the magnetoresistance measurements are detailed in Table I. Table I shows a decrease in MR at higher annealing temperatures, and that the resistivity and the change in resistivity in the presence of a magnetic

TABLE I. Magnetoresistance measurements at $T=4.2$ K for a series of annealed MBE grown $[\text{Co}(11.5 \text{ \AA}/\text{Cu}7 \text{ \AA})_{1.20}/\text{Au}(38 \text{ \AA})]$ multilayers films. The term ρ_s is the saturation resistivity at 4 T and $\Delta\rho$ the change in resistivity between zero applied field and saturation.

Annealing conditions	ρ_s ($\Omega \text{ cm}$)	$\Delta\rho$ ($\Omega \text{ cm}$)	MR(%)
Unannealed	8.2	3.0	36.6
200 °C for 45 min	9.0	3.4	37.8
260 °C for 45 min	12.0	4.4	36.7
290 °C for 45 min	14.4	4.7	32.6
320 °C for 45 min	18.6	5.8	31.1

field doubled for the highest annealing temperature. It is these results that the structural determination using NMR and x-ray scattering should seek to explain.

The ^{59}Co NMR spectra for the unannealed and the most heavily annealed (320 °C for 45 min) MBE grown Co/Cu(111) samples are shown in Fig. 1. It is immediately apparent that no gross changes have occurred as a result of annealing. This is somewhat surprising and demonstrates that Co/Cu(111) multilayers, prepared with a careful choice of substrate and buffer layer structure, are resistant to change up to temperatures in excess of 300 °C. The larger of the two peaks (~ 215 MHz) in Fig. 1 is the NMR line associated with

Co surrounded by 12 Co nearest neighbors (the main line). The smaller peak (~ 168 MHz) in Fig. 1 is the ideal planar interface line where three of the nearest-neighbor Co atoms are substituted by Cu. The intensity between these lines is mostly due to substitution of one or two nearest-neighbor Cu atoms in the interior of the Co layers, although grain boundaries may also contribute to the observed signal in this region. As can be seen from Fig. 1 the main line is shifted to the low-frequency side of the spectrum compared to the value expected for multidomain fcc Co powder. This shift is due to an extensive strain in the plane of the film caused by the lattice mismatch of 2% between Co($a=3.54 \text{ \AA}$) and Cu($a=3.61 \text{ \AA}$).

Although no gross changes occurred as a result of annealing these Co/Cu multilayers, closer examination of the NMR spectra reveals some smaller effects. In order to quantify these effects the experimental data is fitted with a series of Gaussian functions. In the region of interest—150 to 250 MHz—we fit the data with a total of four Gaussians representing the bulk (12 NN Co) first (11 Co+1 Cu) second (10 Co+2 Cu), and third (9 Co+3 Cu) Cu substituted atomic environments. As the first and second substituted environments are not very well defined, due to the lack of intensity, we ensure a consistency of fit over the region by keeping the width, the center position, and the relationship between the amplitudes of these two Gaussian functions constant. In this way we obtain an amplitude scaling parameter that characterizes small differences in the volume of the samples. Hence we are able not only to compare the ratio of the areas under the main and planar interface lines from a single spectrum, but are also able to compare the intensities of the main and planar interface lines between spectra. As the area under a line is directly related to the number of atoms in the particular environment, it is possible to examine how the number of atoms in both the bulk and planar interface line change as a result of annealing. This assumes, as is the case here, that the spectrometer is in an identical configuration for each spectrum.

FIG. 1. ^{59}Co spin echo spectra for Co/Cu(111) multilayer films with structure sapphire/Nb(60 Å)/Cu(30 Å)/[Co(11.5 Å/Cu7 Å) $_{1.20}$ /Au(38 Å)] (a) unannealed (b) annealed at 320 °C for 45 min. All data taken at 4.2 K and corrected for ω^2 and variations in the spin-spin relaxation time T^2 . The arrow shows the position of the center of the NMR line from unstrained fcc Co powder.

FIG. 2. Ratio of main to planar interface line intensity, and the normalized interface line area as a function of annealing temperature. The trend in the ratio is clear and shows a decrease in the number of atoms in the ideal atomic environment relative to the bulk. This interpretation is confirmed by the decrease in the area under the interface line.

FIG. 3. Center frequency of the main and planar interface NMR lines changes as a function of annealing temperature. The interface line frequency remains constant whereas the main line frequency increases. It is worth pointing out that this increase in frequency is independent of the details of the model used to fit the spectra. The uncertainty in the fit of the center frequency is 50 kHz.

Figure 2 shows both the main/planar interface line ratio and the integrated area under the planar interface line as a function of annealing temperature. The ratio of the main/planar interface line increases with annealing temperature. This could be due to either an increase in the relative number of atoms in the bulk environment or a decrease in the number of atoms in the planar interface environment. Examination of the intensities of the interface line shows that the latter is true. The area under the main line does not systematically change and remains approximately constant. Thus we conclude that some small deterioration of interfacial quality has occurred as a result of annealing.

Changes in the position of the main and planar interface lines are shown in Fig. 3. The planar interface line remains constant whereas the main line shows a trend towards higher frequencies at higher annealing temperatures reflecting changes in strain in the interior of the Co layers. The effect of lattice strain can be estimated from high-pressure measurements on fcc Co powder which show that the NMR frequency is increased by 0.106 ± 0.01 MHz/kbar. As mentioned in the introduction the Co lattice will be extensively strained in the plane, although the shift in frequency is never as great as would be predicted for a uniform volume expansion in three dimensions.⁶ This is presumably because of contraction normal to the film plane. The shift in the NMR main line can be expressed in terms of an equivalent hydrostatic pressure, as shown in Table II.

The results in Table II show a clear trend in that all the samples show less strain following annealing. This is consistent with the finding that the amount of planar interface reduces with annealing, as less planar interface implies less

TABLE II. ⁵⁹Co NMR main line frequency and equivalent hydrostatic pressure as a function of annealing temperature. Unstrained fcc Co powder has a center frequency of 217.4 MHz.

Annealing conditions	Main line frequency (MHz)	Equivalent hydrostatic pressure (kbar)	Pressure change on annealing (kbar)
Unannealed	214.28	-29.4	0
200 °C for 45 min	214.39	-28.4	1.0
260 °C for 45 min	214.84	-24.2	5.2
290 °C for 45 min	215.07	-22.0	7.4
320 °C for 45 min	214.63	-26.2	3.2

epitaxial registry and so less strain in the interior of the Co layers. A similar strain relaxation, following annealing, has been observed in sputtered Co/Ag multilayers¹⁰ although the effects in this material were substantially larger.

Details of the x-ray work on these samples is presented elsewhere,⁴ and in this article we shall be content to quote the major results. The x-ray data show no dramatic changes in the specular reflectivity profile. This is consistent with the NMR data where no gross changes were found in any of the spectra. The x-ray data showed significant changes in the Au capping layer as the annealing temperature approached 300 °C, in that a AuCu alloy formed between the Au and the top Cu layer of the multilayer. In order to confirm that a AuCu alloy that formed, a further multilayer with a Co capping layer was grown and annealed at 320 °C. The x-ray scattering data from this sample showed very little change as a result of annealing. The formation of this alloyed capping layer with its higher resistivity accounts for the large changes in measured resistivity. These changes occur because the resistance of this layer both adds in series to the resistance of the multilayer, and is spin dependent (Ref. 4).

Field dependent resonance frequency of hysteresis loops in a few monolayer thick Co/Cu(001) films

Q. Jiang, H.-N. Yang, and G.-C. Wang

Department of Physics, Applied Physics, and Astronomy, Rensselaer Polytechnic Institute, Troy, New York 12180-3590

Dynamic responses of magnetic hysteresis loops in a few monolayer (ML) thick Co/Cu(001) films were studied using surface magneto-optic Kerr effect (SMOKE). For a fixed external field strength H_0 , the hysteresis loop area increases as a function of frequency with a power law and reaches a maximum at a resonance frequency Ω_0 . This Ω_0 depends on the external periodic field strength as well as the thickness and roughness of the films. The thickness and roughness parameters were measured quantitatively using high-resolution low-energy electron diffraction. For a fixed film thickness, the Ω_0 in the low field region is highly dependent on H_0 , which is consistent with the prediction from the mean field model. For two Co films with an equivalent thickness but different degrees of film roughness, the resonance frequency Ω_0 is lower for the rougher films in all the field strengths studied. For a fixed field strength, the value of Ω_0 decreases as Co film roughness increases in a few ML regime. The roughness dependency in Ω_0 indicates that the slowing down in the magnetization reversal process is due to the increased film roughness. © 1996 American Institute of Physics. [S0021-8979(96)18208-5]

In recent years, the subject of nonequilibrium phenomena associated with hysteresis responses of a magnetic system under an external oscillating magnetic field has received attention both in theory¹⁻⁵ and in experiment.^{6,7} Effect of surface roughness on hysteresis responses and coercivity is also an interesting topic.⁸⁻¹⁰ In particular, the value of coercivity H_c depends on the time scale of the relaxation process and film roughness. In the past, the dynamic behavior of frequency dependent coercivity or hysteresis loss had been studied for metallic glasses, ferrites, and others.¹¹⁻¹⁴ The study on dynamic behavior in ultrathin ferromagnetic films has only begun recently. For Co/Cu(001) films in a few ML thick regime, it was observed that this system belongs to the Ising spin system and the hysteresis loop area scales with the field strength H_0 and frequency Ω as $A \sim H_0^\alpha \Omega^\beta$ with $\alpha = \beta = 2/3$ in the low field and low frequency regimes.⁷

In this paper, we will present experimental results of the resonance frequency Ω_0 in a few ML thick Co films and its dependence on the applied field strength and film roughness. At Ω_0 the hysteresis loop area reaches a maximum and beyond it the loop area decreases. At Ω_0 , the delay time τ corresponds to a phase lag $\pi/2$ between the magnetization and the applied field, therefore the loop area is a maximum. In the low field regime, the obtained relationship between Ω_0 and H_0 are consistent with the prediction derived from the mean-field theory.³ The decrease in Ω_0 for the rough film compared with the smooth film is consistent with the observation obtained by magneto-optic Faraday rotation images for ≈ 6 ML thick Co/Au(001) films.¹⁵

All experiments were performed in an ultrahigh vacuum (UHV) chamber equipped with high-resolution low-energy electron diffraction (HRLEED),¹⁶ SMOKE,¹⁷ Auger electron spectroscopy (AES), and a sputter ion gun. The Co atoms evaporation, the determination of thickness and deposition rate as well as the calibration of the effective magnetic field have been described.⁷ We deposited Co films on a smooth Cu(001) and a slightly rough Cu(001) substrate. The smooth

Cu(001) substrate was obtained by sputtering at room temperature and then annealing at ≈ 875 K for 30 min. The slightly rough Cu(001) substrate was obtained after light sputtering ($0.22 \mu\text{A}/\text{cm}^2$) without annealing.

For 2.5 ML thick Co films grown on a smooth Cu(001) substrate, the frequency dependent hysteresis loop area A was plotted in Fig. 1 for selected field strengths H_0 . The values of different H_0 noted in the figure are external field strengths H_0 near zero frequency, or the dc field. The insets (a), (b), and (c) in Fig. 1 are measured hysteresis loops for 20 Hz, 75 Hz and 450 Hz at $H_0 = 31.1$ Oe, respectively. When the sweeping frequency increases, the loop shape changes from a squarelike [$\Omega < \Omega_0$, inset (a)] to a rounded square at the four corners [$\Omega \sim \Omega_0$, inset (b)], then to a distorted parallelogram ($\Omega > \Omega_0$, not shown), and finally to a nearly straight line at high frequencies with the average magnetization $\langle M \rangle$ near its initial magnetization status [$\Omega \gg \Omega_0$, inset (c)]. At Ω_0 , the hysteresis loop shapes at three different field strengths H_0 shown in Fig. 1 are all squarelike but rounded at the four corners [inset (b)]. When H_0 increases, the Ω_0 shifts rapidly from a low value = 34 Hz at a low field strength H_0 (20.7 Oe) to a higher value = 125 Hz at a high field strength H_0 (82.8 Oe) as shown in Fig. 2 (filled circles). A similar increase in Ω_0 with the increasing H_0 was observed for the slightly rough Co/Cu(001) film at 2.5 ML equivalent thickness (open circles). This phenomenon can be explained by the following Ising-like model.

The dynamics of hysteresis in a one-component Ising-like system is governed by the time dependent Ginzburg-Landau equation where a double well potential barrier is assumed. When spatial fluctuation is neglected, the time-dependent magnetization M under an external sinusoidal field $H(t) = H_0 \sin(\Omega t)$ can be described by a mean field model¹

$$\tau \frac{dM}{dt} = -(rM + uM^3) + H_0 \sin(\Omega t), \quad (1)$$

FIG. 1. Hysteresis loop area vs frequency at selected field strengths H_0 for ≈ 2.5 ML thick Co films grown on a smooth Cu(001) substrate. The H_0 near dc field and the Ω_0 at different H_0 are indicated in the figure. The insets: hysteresis loop shapes for 20 Hz (a), 75 Hz (b), and 450 Hz (c) when $H_0 = 31.1$ Oe.

where $rM + uM^3$ ($r < 0$ and $u > 0$) originates from a double well potential due to the anisotropy energy. In the low frequency regime, $0 \leq \Omega \leq \Omega_0$, the dynamic coercivity H_c has been derived analytically³ from Eq. (1) as

$$H_c = H_{c0} + K_1 [\Omega^2 (H_0^2 - H_{c0}^2)]^{1/3}, \quad (2)$$

where K_1 is a constant and $H_{c0} = \sqrt{-4r^3/27u}$ is the static coercivity which can be obtained under adiabatic condition ($\Omega \rightarrow 0$). Where the magnetization in an Ising-like system is approximately a constant, the loop A can thus be derived as $A \approx 4 M_0 H_c$, i.e.,

$$A = A_0 + K [\Omega^2 (H_0^2 - H_{c0}^2)]^{1/3}, \quad H_0 > H_c, \quad (3)$$

FIG. 2. Resonance frequency Ω_0 vs the effective field strength H'_0 for ≈ 2.5 ML thick Co films grown on a smooth Cu(001) substrate (filled circles); grown on a slightly rough Cu(001) substrate (open circles). Solid curves are fits using Eq. (4). The insets: the hysteresis loops at 4 Hz for the smooth film (filled squares) and the slightly rough film (open squares).

where K is a constant and A_0 is the static loop area. The assumption of the constant magnetization is consistent with our observation in the scaling regime for a few monolayer thick Co films/Cu(001).⁷

Equation (2) indicates that the threshold H_c is a function of H_0 and Ω . At a fixed H_0 , the threshold H_c will increase from the static value H_{c0} by an amount proportional to a $2/3$ power law of the frequency Ω .¹⁸ By continuously increasing Ω , the dynamic coercivity H_c may pass the H_0 limit; thus, the loop area will reach a maximum value at the resonance frequency $\Omega = \Omega_0$. When Ω increases further, the loop area will decrease because the applied external field strength is not high enough ($H_0 < H_c$) within its time scale to overcome the double well barriers and reverse the magnetization. Replacing H_c by H_0 in the left hand side of Eq. (2), the field dependence of the resonance frequency can be expressed in the following form

$$\Omega_0 = \frac{(H_0 - H_{c0})^{3/2}}{C \sqrt{H_0^2 - H_{c0}^2}}, \quad (4)$$

where $C = K_1^{3/2}$. Note that when $H_0 \sim H_{c0}$, the $\Omega_0 \sim H_0 - H_{c0}$ shows a linear relationship with H_0 . In practice, one must consider the modification of H_0 by the eddy current effect. This correction can be made as the effective field strength H'_0 , which equals H_0 times a calibration factor $g(\Omega)$. Replacing H_0 by the effective field strength H'_0 , we used Eq. (4) to fit our resonance frequency data for both smooth and slightly rough films shown as solid curves in Fig. 2.

In the low field and low frequency regimes, Eq. (4) indicates that the value of Ω_0 is dependent on the applied field strength H_0 and static coercivity H_{c0} . For 2.5 ML thick films, at $\Omega/2\pi = 4.0$ Hz, the dynamic coercivity H_c (40.0 Oe) is larger in the slightly rough film (open squares in the inset of Fig. 2) than that (15.0 Oe) on the smooth film (filled squares in the inset of Fig. 2). The static coercivity H_{c0} can be obtained by extrapolating Ω_0 to $\Omega_0 = 0$ of the solid lines, the static coercivities H_{c0} are 4.3 Oe and 40.5 Oe for the smooth film and rough film, respectively. The change in the static coercivity H_{c0} value results in the difference in values of Ω_0 between the smooth and slightly rough films shown in Fig. 2, which is consistent with the description of Eq. (4). Note that in both 2.5 Co/Cu(001) films, the hysteresis loop shapes shown in the insets of Fig. 2 indicate a narrow distribution of coercivity H_c over islands ($H_c \pm 3.0$ Oe for the smooth film and $H_c \pm 6.0$ Oe for the rough film). If we assume that the distribution of H_{c0} is the same as that of H_c , the fit values of Ω_0 displayed in Fig. 2 will be affected by ± 5.0 Hz. In addition to the static coercivity H_{c0} , the surface roughness of the deposited film may play a role in the value of Ω_0 and is discussed in later paragraphs.

The plot of Ω_0 vs H_0 in the high field strength region deviates from the fit curves (solid curves) using Eq. (4) (see Fig. 2). This may be due to the fact that the scaling law described by Eq. (3) is not valid at high field strength and high frequency regions.⁷

Note that the magnitude of the value of resonance frequency Ω_0 is quite different from that of the switching frequency Ω_s , which is equal to the inverse of t_s , the time period required for the magnetization M (or magnetic induc-

FIG. 3. Resonance frequency Ω_0 vs Co films thickness (open circles). These films were grown on a slightly rough Cu(001) substrate. The external field strength was fixed at a dc equivalent field $H_0=103.0$ Oe for all measurements. The inset: the interface width w (filled squares) as a function of Co film thickness.

tion B) to change from 0.1 to 0.9 of the total change ΔM (or ΔB).¹⁹ Roughly speaking, t_s is the time period for M to jump from P_1 to P_2 as shown in the inset (a) of Fig. 1. Switching speed study usually requires a dc bias field H_b to be added to a pulse field system to allow the higher coercivity samples to be switched from saturation to zero remanence.²⁰ The Ω_0 defined in our study is related to the inverse of the time period in which magnetization responds to a sinusoidal periodic magnetic field when the magnetic field changes in a complete cycle of $-H_0 \rightarrow 0 \rightarrow H_0 \rightarrow 0 \rightarrow -H_0$. The physical significance of the Ω_0 is that there is a symmetry breaking of the average magnetization at the $\Omega=\Omega_0(H_0)$, i.e., $\langle M(t) \rangle = 0$ for $\Omega < \Omega_0(H_0)$ changes to $\langle M(t) \rangle \neq 0$ for $\Omega > \Omega_0(H_0)$; within the time period of $1/\Omega_0$, the magnetization can still make excursions between two minimum states without losing its amplitude, and beyond it the average magnetization is a non-zero value ($\Omega > \Omega_0$) and the magnetization prefers to stay near its initial magnetic status ($\Omega \gg \Omega_0$).⁷

For a few ML thick Co films grown on a slightly rough Cu(001) substrate, the Ω_0 value under a dc equivalent field $H_0=103.0$ Oe shown in Fig. 3 (filled circles) decreases rapidly from 94 Hz at 1.0 ML to 83 Hz at 3.0 ML, and then decreases further to 80 Hz at 6.0 ML. The measured coercivity H_c is nearly constant (40.0 Oe) in this thickness regime.¹⁸ This implies that the change in Ω_0 as a function of thickness for the slightly rough film may not be caused by H_c . Note that in this thickness regime, the surface roughness parameters do change their values and may relate to the change in Ω_0 . We extracted the changes in roughness parameters in a few ML Co films, i.e., the interface width w , roughness exponent α , and the lateral correlation length ξ ^{18,21} by the analysis of the energy dependent angular profiles ($I-V$) of the (00) beam using HRLEED. The result is shown in the inset of Fig. 3. The interface width w (filled squares) increases from $0.39t$ for a slightly rough but clean Cu(001) surface to $0.61t$ for a 5.0 ML thick Co film, where t is a single step height (1.76 Å for the Co film). The change in the

α value with Co film thickness also exhibits a continuous drop from 0.57 ± 0.02 at 1.0 ML to 0.44 ± 0.02 at 5.0 ML thick (not shown). A smaller value of α corresponds to a more locally rugged surface. The lateral correlation length ξ shows only a small change from 218 ± 5 Å on a slightly rough Cu(001) surface to 182 ± 5 Å for Co films at 3.0 ML thick (not plotted). Another observation is that, for 2.5 ML thick Co films shown in Fig. 2, the maximum Ω_0 (85 Hz) in the slightly rough film ($w=0.52t$, $\alpha=0.49$, $\xi=190$ Å, open circles) is lower than that (125 Hz) in the smooth film ($w=0.49t$, $\alpha=0.61$, $\xi=250$ Å, filled circles). These data in Figs. 2 and 3 indicate that the resonance frequency Ω_0 decreases when surface roughness increases.

In submonolayer regime, a recent magnetic lattice gas model calculation of dynamic hysteresis of magnetic islands predicts that the value Ω_0 depends on the lacunarity of each magnetic island.²² The results of the model indicate that the net exchange energy associated with the edge moments in magnetic islands affects the value of Ω_0 . Extension of this model to several monolayer thick ferromagnetic films is highly desired. In addition to the changes in the exchange energy, local defects can also modify the magnetic anisotropy energy, thus these defects create hard magnetic centers in which the magnetization reversal process slows down and manifests itself through the increased coercivity and reduced Ω_0 . The slowing down of the magnetization reversal in ≈ 6 ML thick Co/Au(001) rough films was also observed by magneto-optic Faraday rotation images in which a lacunar domain structure evolved slowly towards a uniformly reversed magnetic state.¹⁵

Fe adsorption and film growth on GaAs(001) (2×4)-As (abstract)

E. Kneedler, P. M. Thibado, B. T. Jonker, B. R. Bennett, L. J. Whitman,
B. V. Shanabrook, and J. J. Krebs
Naval Research Laboratory, Washington, DC 20375-5343

We have examined the initial interface formation and subsequent film growth for Fe films on the As-terminated (2×4) reconstructed surface of GaAs(001) in an effort to correlate the initial adsorption sites and film growth with the magnetic anisotropy. The growth and surface studies were performed in a four chamber ultrahigh vacuum system which incorporates UHV sample transfer between the chambers for III-V semiconductor growth, metal growth, photoelectron diffraction (PED), and scanning tunneling microscopy (STM). After coating with a thin film of Au (40 Å) at room temperature, the samples were removed from the system for postgrowth characterization, which included ferromagnetic resonance and magnetometry. The GaAs(001) surface was prepared via homoepitaxial growth by MBE, with the growth terminated in a manner which resulted in a well-ordered As-dimer terminated (2×4) reconstructed surface as revealed by reflection high energy electron diffraction and STM. Fe deposition was performed in a second MBE chamber for coverages which ranged from 0.1 ML to several tens of monolayers at a substrate temperature of 175 °C. The sample was then transferred under UHV to either the PED or STM chamber to determine the initial adsorption sites, growth mode, and evolution of film structure with increasing coverage. For the lowest coverages studied (0.1 ML), we obtain evidence for preferential adsorption at As-dimer sites. At a coverage of 1 ML, two-dimensional islands form approximately 20 Å in size, but elongated along the missing dimer rows with an aspect ratio of 2:1. At high coverages (>40 Å), we observe three-dimensional mounds or clusters with an average in-plane diameter of approximately 100 Å and a narrow size distribution. Even at this coverage, the monolayer terraces of the GaAs substrate are clearly visible in the STM image, with the Fe film uniformly growing on each terrace. Photoelectron diffraction in the forward scattering regime (high electron kinetic energy) is utilized to determine the growth mode. At low kinetic energy, information on the adsorption site is obtained from Auger electron diffraction and compared with the results of the real space STM images. [S0021-8979(96)42508-9]

Magnetic properties and Pd–H miscibility gap in Ni/Pd composite fine particles

Takashi Manago, Yoshichika Otani,^{a)} and Hideki Miyajima

Department of Physics, Faculty of Science and Technology, Keio University, Hiyoshi 3-14-1, Kohoku, Yokohama 223, Japan

Etsuo Akiba

National Institute of Materials and Chemical Research, Tsukuba, Ibaraki 305, Japan

The magnetic and structural properties of Ni fine particles coated with Pd were investigated in hydrogen atmospheres by means of *in situ* magnetometry and *in situ* x-ray diffractometry. The x-ray diffraction patterns in hydrogen atmospheres show that the width of the plateau in the Pd–H phase boundary (miscibility gap) narrows with decreasing Pd thickness, which is reminiscent of nano-crystalline Pd. At room temperature, the magnetization in hydrogen atmospheres shows a steep saturation and a small decrease in the residual magnetization, indicating that the interface magnetic anisotropy is reduced by the hydrogenation. © 1996 American Institute of Physics. [S0021-8979(96)18308-1]

I. INTRODUCTION

The susceptibility χ of Pd is the largest in the 4d transition metal series.¹ This is due to a high exchange enhancement. The Stoner enhancement factor is 9.3.² Though Pd is a paramagnet, it is nearly a ferromagnet. If an additional strong exchange enhancement acts on Pd, the paramagnetic Pd may turn ferromagnetic.³ Also, Pd metal absorbs a large amount of hydrogen and χ depends on the hydrogen concentration. Specifically, χ decreases with increasing hydrogen concentration and goes to zero at PdH_{0.6}. Further increase of hydrogen results in a negative susceptibility.¹ This is because the donor electrons from H atoms enter the 4d band of Pd, and χ is thereby depressed.

The properties of the hydride PdH_x, characterized by the pressure-concentration isotherms, the so-called *p*–*x*–*T* curves, show a phase separation between the solid solution (α) and the hydride (β) and a plateau at the phase boundary (miscibility gap). The *p*–*x*–*T* curves of the PdH_x were believed to be independent of the particle size. However, recent studies on nanocrystalline Pd particles demonstrated that the plateau was narrowed by diminishing the size of the particles.^{4–6} This suggests that the narrowing of the plateau is somehow associated with the increased contribution of the surface relative to the volume.

We have been investigating the magnetic and structural properties of spherical Ni particles coated with Pd. The average diameter of Ni sphere is 0.7 μm and the thickness of the Pd shell is a few tens of nm. Previous studies^{7,8} showed that the Pd shell seemed magnetically polarized through the exchange coupling with Ni at the interface, whereby weakly ferromagnetic properties appeared in the Pd shell at low temperatures. There was also observed a remarkable effect of hydrogenation that depressed the above mentioned ferromagnetic behavior of the Pd shell.

In this study, we performed *in situ* magnetization and x-ray diffraction measurements in hydrogen atmospheres so

as to obtain more detailed information on magnetic and structural properties of the Ni/Pd particles.

II. EXPERIMENTAL PROCEDURE

Five samples with different weight of Pd (5, 10, 15, 20, and 30 wt %) were prepared by chemical reduction method.⁷ Hereafter, we call these samples, according to their Pd wt %, NP05, NP10, NP15, NP20, and NP30, respectively. The average thickness of the Pd shell for each sample is tabulated in Table I. For comparison, the coarse-powdered Pd (C–Pd) was also prepared.

The change in the lattice parameter of Pd shell was measured under hydrogen pressure from 0.1 to 30.0 atm at 295 K by means of *in situ* x-ray diffractometry (XRD) using CuK α radiation ($\lambda=0.1542$ nm). The sample was mounted inside a pressure chamber with beryllium windows. While evacuating the chamber, we first measured diffraction patterns in the angular range $36^\circ \leq 2\theta \leq 56^\circ$, which include the (111) reflection from the Pd shell and the (200) reflection from the Ni core. Hydrogen gas (7N) was then introduced into the pressure chamber until the pressure rose to 30.0 atm. The pressure decreased by about 0.1% because of the hydrogen absorption of the Pd shell and finally achieved its equilibrium after about 5 min. Then x-ray diffraction patterns were obtained in the same angular range. The hydrogen pressure was then reduced to the desired pressure and was kept for about 5 min. The same experimental routine was repeated for the different samples.

TABLE I. Weight percent of the Pd and average thickness of the Pd layer of the Ni/Pd composite particles. The average diameter of Ni particles is (0.7 \pm 0.2) μm .

Sample No.	Weight of Pd (wt %)	Average thickness of Pd (nm)
NP05	5.39	4.8
NP10	11.05	10.2
NP15	15.95	15.4
NP20	21.83	21.0
NP30	32.35	36.6

^{a)}Present address: Department of Materials Science, Faculty of Engineering, Tohoku University, Sendai 980, Japan.

Magnetization measurements were carried out in a hydrogen atmosphere using a vibrating sample magnetometer (VSM) at room temperature (298 K) in magnetic fields up to 12 kOe. The vibrating rod, specially constructed for the *in situ* magnetometry, consists of a glass tube connected to a copper tube and a nonmagnetic sample holder made of synthetic resin (Dyfreon). Through the vibrating rod, the hydrogen gas can be introduced into the sample space during the magnetization measurement. In order to subtract a signal from the sample holder, each sample was measured in both hydrogen and dry air atmospheres.

In order to study the miscibility gap, the p - x - T curve was measured for NP15 and C-Pd at 373 K in the hydrogen gas pressure up to approximately 10 atm.

III. RESULT AND DISCUSSION

In the previous work,⁷ the lattice parameter of Pd in the Ni/Pd composite particles was unchanged by hydrogenation. There are two possible explanation for this result; one is that there is an isovolumetric constraint during hydrogenation and the other is that the absorbed hydrogen desorbs even at the room temperature as soon as the particles are exposed into the air. Our recent electrical resistivity measurements in a hydrogen atmosphere support the latter explanation. The equilibrium state was achieved within 5 min, suggesting that the surface barrier inhibiting the desorption of the hydrogen is very low. A significant portion of the hydrogen stored in the Pd shells must have desorbed during the x-ray diffraction measurements. In order to clarify this point, we performed the *in situ* x-ray diffraction measurement in hydrogen atmosphere.

The XRD patterns show no trace of any mixing of Ni and Pd at the interface. Before hydrogenation, the lattice parameter of the Pd layer is 0.3889 nm, which is the same as that of the C-Pd. The XRD patterns for NP15 under various hydrogen pressures are shown in Fig. 1. No shift was observed in the position of the diffraction peaks from the Ni core, indicating that Ni core hardly absorbs any hydrogen. On the other hand, the Pd shell transforms into the β -Pd phase, and the Pd lattice dilates about 3%–4%. By reducing the hydrogen pressure to zero, the lattice parameter of the Pd shell returned to the value before hydrogenation. A linear relationship between the Pd lattice parameter and logarithm of the hydrogen pressure was obtained as shown in Fig. 2. Interestingly, the change in the lattice parameter depends on the thickness of the Pd shells, and the lattice parameter is smaller for the thinner shells. The hydrogen concentration x in the Pd shell was determined from the linear relation between the lattice parameter of the Pd and the hydrogen concentration. According to Schirber and Morosin,⁹ the lattice parameter a is given by $a(x) = 0.4025(1 + 0.044(x - 0.6))$ nm. The hydrogen concentration evaluated from the above relation is indicated on the upper axis in Fig. 2. The figure clearly shows that the width of the plateau at the Pd-H phase boundary significantly narrows as the thickness of Pd shell diminishes. The p - x - T curve for NP15 and C-Pd also show that the amount of the hydrogen in the β phase is reduced, that is, the width of the plateau of NP15 becomes narrower than that of C-Pd.

FIG. 1. XRD pattern of one of the samples, NP15, in hydrogen pressures, wherein the reflection from Be is due to the Be sample holder. The XRD measurement was performed sequentially from (a) to (e).

The above mentioned hydrogenation characteristics is quite similar to that observed in nanocrystalline PdH_x , the surface of which plays an important role in determining the width of the plateau.⁶ Monte Carlo simulation⁶ of the p - x - T curves of nanometer-size Pd clusters under hydrogen loading showed that the surface was first loaded with hydrogen and then the interior. This resulted in the narrowed plateau. Considering the large surface area of the Pd shells of the Ni/Pd composite particles, we may apply the same explanation to our case.

The magnetization curves of Ni/Pd particles in dry air and hydrogen atmospheres are shown in Fig. 3, together with the difference of the magnetization $\Delta M = M_{(\text{hydrogen})} - M_{(\text{dry air})}$ as a function of magnetic field. The difference in magnetization ΔM approaches zero and become slightly negative with increasing magnetic field. That

FIG. 2. Hydrogen pressure dependence of the Pd lattice parameter (lower x-axis) and the hydrogen concentration (upper x-axis).

FIG. 3. Magnetization curves of Ni/Pd particles (NP15) in a dry air (a) and in a hydrogen atmosphere (b). The magnetization difference between the magnetization taken in a dry air and in a hydrogen atmosphere, $\Delta M = M_{(\text{hydrogen})} - M_{(\text{dry air})}$ (c).

is, the saturation magnetization of Ni/Pd composite particles after hydrogenation is smaller than before hydrogenation. However, the contribution from the magnetically polarized Pd shell to the magnetization is small at room temperature. The magnetization curve of the hydrogenated Ni/Pd particles exhibits a steep increase toward saturation and the residual magnetization is decreased by about 0.3–0.4 emu/g.

These results imply that the interface anisotropy between the Ni core and the Pd shell is suppressed by the hydrogenation since the Ni core hardly absorbs hydrogen at the low pressure of a few tens of atm. The evaluated change in magnetic anisotropy energy per unit area from the difference between two magnetization curves, ΔK , is about $-(2-2.5) \times 10^{-2}$ erg/cm², which is independent of the thick-

FIG. 4. Pd thickness dependence of the change in the magnetic anisotropy energy, ΔK , per unit interface area between the Ni core and the Pd shell.

ness of Pd shell, as shown in Fig. 4. The change of the magnetic anisotropy may be closely related to the change in the elastic energy at the interface, coupled with the Pd lattice expansion due to the hydrogenation. Further investigations are required in order to clarify the effect of the hydrogen on the interface anisotropy.

ACKNOWLEDGMENTS

We would like to express our gratitude to H. Sakamoto, Tanaka Kikinzoku, Inc., for giving us detailed information about the Ni/Pd composite particles. We also thank M. Yoshida, Hitachi Chemical Co. Ltd., for his assisting in *in situ* x-ray diffraction measurements. This work was partly supported by the Grant-in-aid for Scientific Research from the Ministry of Education, Science, Sport and Culture in Japan.

Magnetic impurities and clusters on Ag, Pd, and Pt surfaces (abstract)

V. S. Stepanyuk

The modern STM technique allows to manipulate the structure of small clusters on surfaces and to produce one- or two-dimensional nanostructures. It can be speculated that due to the reduction of coordination number many of these clusters containing transition elements are magnetic. In this paper we will show that small clusters of 3d, 4d, and 5d atoms are magnetic on different substrates. Our calculations are based on density functional theory and a newly developed KKR Green's function method for defects at surfaces.¹ We calculate the magnetic properties of several linear chains (*C*) and plane islands (*I*) of 4d and 5d adatoms. In particular we consider linear chains of 2 (dimers, *C*₂), 3 and 4 adatoms (*C*₃ and *C*₄), being oriented in (110) direction, as well as three compact islands with 4, 5, and 9 adatoms (*I*₄, *I*₅, and *I*₉). The moments of the dimers are in general reduced by the interaction in comparison to the moments of single adatoms.¹ In most cases both a ferromagnetic and an antiferromagnetic configuration exist, with the ferromagnetic one being more stable at the end and the antiferromagnetic one at the beginning of the series. For the linear chains quite large moments are obtained, but the behavior with size is nonregular. The large moments obtained for all four chain structures indicate that also infinite chains of these atoms should show appreciable moments. For compact islands (*I*₄, *I*₅, and *I*₉) the hybridization effects within the cluster are even larger. For Ag(001) we find only appreciable moments for the Ru and Rh nanostructures. © 1996 American Institute of Physics. [S0021-8979(96)42608-8]

The structure and properties of Co–N and Co–O based films, prepared by rf magnetron reactive sputtering using nitrogen or oxygen and argon gases, have been studied. Transmission electron microscopy (TEM) observation reveals that each Co–(Al or Si)–(N or O) film is a typical film with granular structure, with grain size less than 5 nm. It is found by micro-focused energy-dispersive x-ray and electron energy loss spectroscopy analysis that the grains are mainly composed of Co and the intergranular regions are ceramics of N or O. In Co–N based films, soft magnetic properties are found in both Si and Al containing films over a wide range of film preparation conditions and compositions. Only the films with Al show soft magnetic properties in Co–O based films, which have ρ of 500–1000 $\mu\Omega$ cm, H_k of about 80 Oe and B_s of about 10 kG. By adding about 10 at. % Pd, the soft magnetic properties and H_k of Co–O based films are significantly improved, with H_k more than 180 Oe. These films exhibit a remarkable constant frequency response of the permeability up to around 500 MHz, which is approximately explained by the Landau–Lifshitz formula.

I. INTRODUCTION

Recent improvements in electronic devices have led to a demand for further miniaturization and higher frequency operation of magnetic devices. One of the important properties of magnetic materials required for such applications is the frequency (f) response of permeability (μ), which is limited by eddy current loss and resonance. According to the modified Landau–Lifshitz equation, which predicts the μ - f response, large values of saturation magnetization (M_s), electrical resistivity (ρ) and anisotropy field (H_k) are required for magnetic materials to show an excellent μ - f response.¹ Soft magnetic films studied to date have large B_s , but exhibit a poor frequency response, assuming sufficient film thickness (d) for such applications, primarily due to their low ρ and H_k .^{2–4}

A well-known method for reducing eddy current loss is to laminate soft magnetic thin films with insulating layers, i.e., constructing multilayers.⁵ However, the μ - f response of multilayers is not improved as much as expected for the thickness of the isolated magnetic layers. Another method is to increase ρ of the magnetic film. Recently, Fe-based films with a two-phase hetero-amorphous or granular structure have been found to possess both large ρ and soft magnetic properties.^{6–8} Unfortunately, these films also show a poorer μ - f response than expected from their large ρ . The reason is the low values of H_k in the films. There has not been any consideration of H_k in preparing these soft magnetic materials. Hence, if soft magnetic films which possesses high ρ and B_s as well as reasonably large H_k could be realized, they can be expected to exhibit an excellent μ - f response and prove to be the most suitable material for the above applications.

To realize such films, we have tried to synthesize Co based films with granular structure.^{9,10} The advantage of a granular film is that the particle size, and consequently the magnetic properties, can be tailored by adjusting the method of deposition and the preparation conditions. And the interparticle material may also be controlled by considering the values of the heat of formation for the substances both of the particles and the interparticle regions. Cobalt based alloys are known to exhibit zero magnetostriction¹¹ and an induced magnetic anisotropy.¹² Then, if the size of the particles and the thickness of the interparticle region for Co based granular films can be controlled arbitrarily, we can prepare soft magnetic films with large B_s , H_k , and ρ .

In this article, we will describe the results of synthesizing a variety of Co based granular films, expected to have large H_k and ρ and to be magnetically soft, and emphasize the relationship between the structure and magnetic properties, in particular, a high-frequency response of permeability.

II. EXPERIMENT

Granular metal films have been produced by a variety of means, including evaporation, co-sputtering of a metal, and an insulator, and sequential sputtering of a metal and an insulator.¹³ Each method has advantages and disadvantages. All of the films discussed in this work were prepared by sputtering an alloy target in a reactive gas. Such a reactive sputtering method using an alloy target is best for controlling closely the concentration of gas elements and for obtaining films with homogenous composition. However, in this method there are some compositional limitations on the films, attributable to the preparation of the alloy target. The

FIG. 1. Curves of the coercivity for as-deposited Co-ME-O films vs O_2 gas flow ratio in a sputtering gas (target: $Co_{85}ME_{15}$, ME=Co, Al, Ge, Si, Sn).

composition of our alloy targets has been mainly selected by consideration of the difference of the heats of formation between the Co-(N or O) compound and the oxide or nitride of the second elements (ME). Therefore, Co-ME (ME=Al, Si, B, Ge, or Sn) alloy plates were used as targets.

Films were prepared by rf reactive magnetron sputtering with (O_2 or N_2)+Ar gases in a background pressure better than 3×10^{-7} Torr. During sputtering, a static magnetic field of about 100 Oe was applied parallel to the substrate plane in order to induce an in-plane uniaxial anisotropy in the films. The composition of films was mainly measured by Rutherford backscattering spectrometry (RBS) with He^{2+} ions of 2 MeV energy. Film structures were investigated by x-ray diffraction (XRD) and micro-focused high-resolution transmission electron microscopy (HRTEM), with energy dispersive x-ray analysis (EDX) and electron energy loss spectroscopy (EELS). Magnetization vs field was measured with a vibrating-sample magnetometer (VSM). The permeability from 1 to 500 MHz was determined by both figure of eight and parallel line methods.¹⁴ The electrical resistivity was measured by the conventional four-point probe method. As substrate materials, glassy carbon plate, NaCl single-crystal and Corning #7059 glass (0.5 mm in thickness) were used for RBS analysis, TEM observation, and other measurements, respectively.

III. RESULTS AND DISCUSSION

A. Effects of ME elements

In order to find the suitable ME elements to show soft magnetic properties at high frequency, films have been systematically prepared under varying sputtering conditions (mainly, sputtering gas pressure and gas flow ratio of O_2 or N_2 in Ar), and changing target compositions. Figure 1 illustrates the variation in H_c for Co-ME-O films with changing O_2 gas flow ratio in the sputtering gas. It is noted that only the films containing Al show soft magnetic properties in a

FIG. 2. X-ray diffraction patterns of the granular $(Co_{0.85}Al_{0.15})_{100-x}O_x$ films with varying O concentration.

limited range of O_2 ratio, and H_c of other films is over 10 Oe. In the case of N based films, on the other hand, the films with not only Al but also Si show soft magnetic properties over a wider N concentration range than that of O based films. These results may be related to the microstructure of the films and, consequently, to the difference of the heat of formation between Co-(N or O) and ME-(N or O) compounds.¹⁵

In what follows, attention is mainly focused on films containing Al, which show soft magnetic properties in both Co-N and Co-O films, and have the largest difference of heat of formation between Co-(N or O) and Al-(N or O) compounds in this series.

B. Microstructure

Figure 2 shows the x-ray diffraction patterns of Co-Al-O films with different oxygen concentrations. The structure of soft magnetic films is basically fcc phase (α -Co), while hcp phase (γ -Co) is observed in Co-ME-O films not showing soft magnetic properties. The width of the diffraction peaks becomes wider and the peak height decreases drastically with increasing O content in films between 20 and 50 at. % O. From the Scherrer formula,¹⁶ the particle size can be estimated from the x-ray diffraction patterns, and the results suggest that a granular structure may be realized in films in this range of O content. With a further increase of oxygen content above 50%, Co-O phase with considerably coarse particle size was observed.

To reveal the structure variation of these films more clearly, we performed TEM observation of Co-(N or O) based films. TEM is an ideal tool for the investigation of the size and shape distributions of the particles in a granular sample. A micrograph of the particle structure of Co-Al-O

FIG. 3. TEM images of the Co-Al-O granular films containing different amounts of O (target: $\text{Co}_{85}\text{Al}_{15}$).

films deposited from a $\text{Co}_{85}\text{Al}_{15}$ target is shown in Fig. 3. A clear granular structure is observed in the films with a considerable amount of oxygen (30–50 at. % O). The particles are seen to be of relatively narrow size distribution, to be roughly spherical in shape and to be under 50 Å in diameter. The films containing more than 50 at. % O are seen to consist of an oxide phase with large lattice constants and particle diameters. Electron diffraction ring patterns were observed, and found to be in good agreement with the x-ray diffraction results. The interparticle materials seem to become clearer with increasing concentration ratio of ME/Co in the target, which suggests the existence of ME ceramics in the interparticle regions.

The same tendency of structure is observed in the Co-Al-N films, where the particle-interparticle interface is not as clear as that for Co-O based films, as reported earlier. It is also observed in Co-N based films that the interparticle regions are more or less in the amorphous state, while the particles contain more clearly a microcrystalline phase.¹⁷

Of considerable interest is the compositional difference between the particle and interparticle materials for these films. The local compositions of several positions marked in Fig. 4 have been investigated by micro-focus EDX and EELS, where the spot diameter is about 2 nm. By comparing the results for the interparticle and particle regions, it is clear that there is considerable compositional difference between them. Specifically, the Al concentration is low in the particle

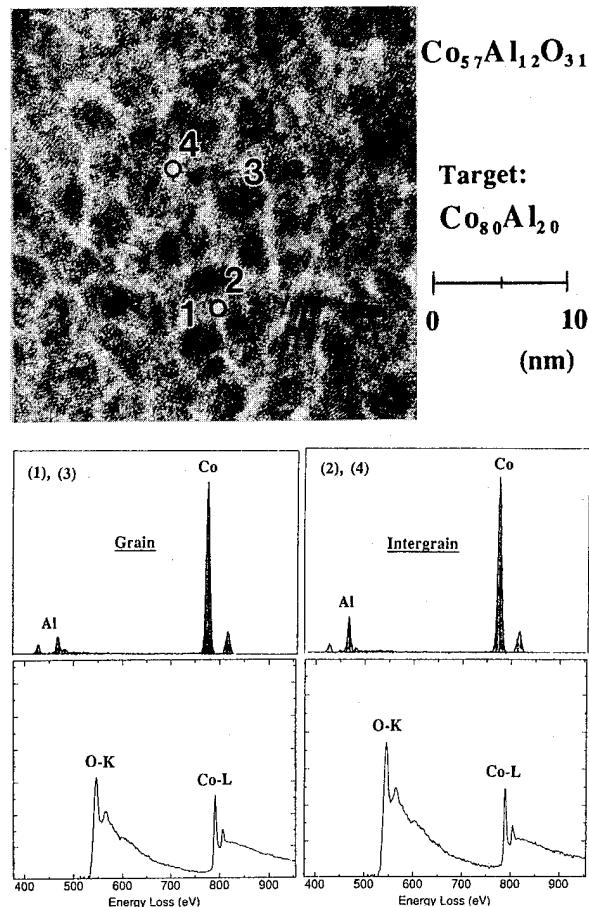

FIG. 4. TEM image and EDX and EELS spectra of grain (1,3) and inter-grain (2,4) regions for Co-Al-O granular film.

but high in the interparticle region; consequently, the Co concentration is high in the particle, but low in the interparticle region. Moreover, the O concentration is high in the interparticle region and low in the particle. These results contain information from not only the spot but also from a little of its surroundings, because the spot size of the electron beam is large compared to the width of the interparticles regions and electrons are scattered by the surface roughness of the film. Therefore, the actual composition of the particle and interparticle regions are thought to be more clearly separated than shown in Fig. 4; that is, the particles consist mainly of a Co based alloy and the interparticle regions of (O or N) ceramics. Analysis of the local composition of Co-N based films is more difficult than that of Co-O based films, as the interface between the particle and the interparticle regions is not as clear and the size of particles is smaller than that of Co-Al-O films. This analysis has not yet been performed.

These results for the local composition support the previous hypothesis about the preferential oxidation of Al during deposition and the formation of Al-O materials in the interparticle regions. And these hypotheses are also useful when considering the explanation for the high electrical resistivity and magnetic properties of the present films, as will be discussed later.

FIG. 5. Relationship between electrical resistivity and O_2 gas flow ratio in sputtering gas for various Co-Al-O films (targets of Co:Al=90:10, 87:13, 85:15, 80:20).

C. Transport properties

We measured the electrical resistivity at room temperature of each series of samples. The result of these measurements is shown in Fig. 5 for Co-Al-O granular films as a function of the flow ratio of O_2 gas. As one expects, there are two steps of the increment of the resistivity versus O_2 ratio, that is, metal-to-nonmetal transitions. The first increment, at lower O content, corresponds approximately to the formation of the granular structure, which is attributed to the preferential oxidation of Al. In well-known granular materials, it is called the percolation threshold,¹⁸ where metal particles become so dilute that they no longer form a conducting path. In the case of this series, the value of ρ is under $10^3 \mu\Omega \text{ cm}$, since the Al concentration of the targets is substantially lower than that of common granular materials where there may be some conducting path because of their much smaller interparticle layer thickness. On the other hand, for Al concentrations higher than 20 at. % in the target, the value of the resistivity for the films is higher than $10^4 \mu\Omega \text{ cm}$. These results also support the existence of Al-O materials in the interparticle regions. The reason for the second rapid increment of ρ may be the oxidation of Co, and the value exceeds $10^8 \mu\Omega \text{ cm}$. Almost the same results are observed in the case of Co-Al-N films. The first increment of ρ is sharper than that of Co-Al-O films,¹⁷ but its magnitude is not as high. The difference in the ρ values between the O and N systems is attributed to the differences in the morphologies and the interparticle materials of the two systems.

To reveal the relationship between ρ and composition, contours of ρ in the ternary Co-Al-O system films are shown in Fig. 6. As one can see, a large ridge of resistivity is found near 17 at. % Al. It is worth noting that the composition of this ridge is almost the same as the Al_2O_3 stoichiometric chemical composition. In Co-Al-N films, a ridge of ρ is observed at the stoichiometric composition AlN (1:1). These results also support the belief that the interparticle regions mainly consist of Co and Al based ceramics in these granular films, and are in agreement with Ref. 18, which reports that the chemical shift of the Al^{2P} peak is largest when the ρ of films is maximum.

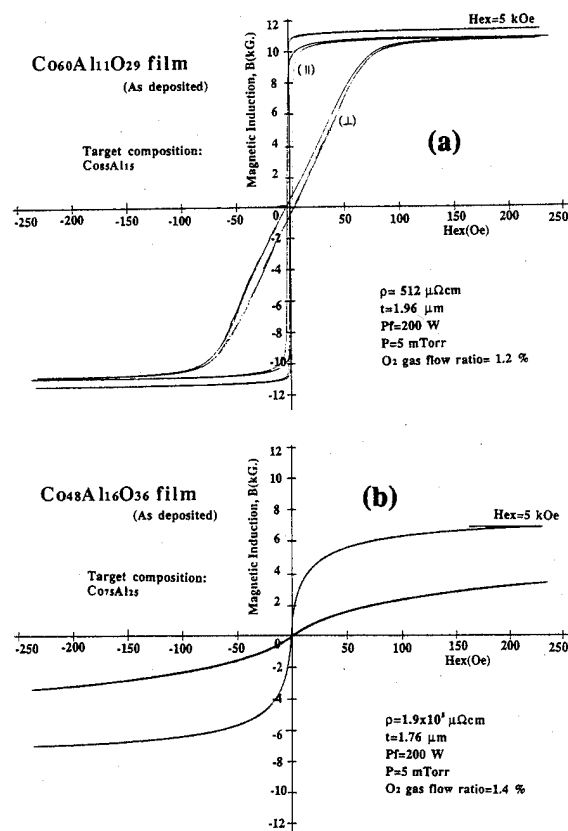

FIG. 6. Contours of the electrical resistivity for Co-Al-O films (dashed line: Al_2O_3 composition).

D. Magnetic properties

Typical magnetic hysteresis loops of Co-Al-O granular films measured at RT are shown in Fig. 7, where Fig. 7(a) is the result using a $Co_{85}Al_{15}$ target, and Fig. 7(b), using $Co_{75}Al_{25}$. Keeping in mind that H_c of a pure Co film is about 50 Oe due to magnetic multidomain structure, we find that the granular Co based film has H_c as low as 5 Oe for $Co_{85}Al_{15}$ -O films. The change of H_c with O concentration is similar to the result for ρ shown in Fig. 5. Namely, in films

FIG. 7. Magnetization curves of Co-Al-O film in the as-deposited state [targets: (a) $Co_{85}Al_{15}$, (b) $Co_{75}Al_{25}$].

with a small amount of O, where selective oxidation starts to occur, perpendicular anisotropy with large H_c is observed. On the other hand, films which contain a considerable amount of O and have a ridge of ρ , show soft magnetic properties. Such soft magnetic films have been found across a wide range of preparation conditions for Co-Al-N films. The small value of H_c is attributed to (1) the existence of some magnetic interaction among the particles, the percolation effect, and (2) the phase of particles. Approaching the percolation threshold, the formation of a connecting network of small particles starts to occur. Under such conditions, the particles would prefer a magnetic closure-domain structure due to dipolar interaction, and effectively the system behaves as a multidomain structure even though individual particles still remain single domain. As a result, the magnetic properties are similar to soft magnets.¹⁹ Another reason is the phase of the particles. All the films which exhibit soft magnetic properties are composed entirely of fcc phase with (111) preferred orientation, for which the anisotropy energy is reported to be the lowest.²⁰

As seen in Fig. 7(a), a larger anisotropy field than 80 Oe is attained. The H_k is considered to be induced by the magnetic field during deposition. However, no difference of morphology perpendicular and parallel to the direction of the applied field is detected by TEM observation or an electrical resistivity measurement. An H_k value of 35 Oe at the most is also observed in Co-Al-N films, and is necessary to improve the frequency response of the permeability, as will be discussed later.

For films prepared from targets with Al concentration above 20 at. %, the magnetization does not saturate even in a field of 5 kOe [see Fig. 7(b)]. In such a film, magnetic granular particles seem to be isolated and protected by the non-magnetic matrix. These ultrafine particles can be considered as an noninteracting assembly of single domain particles or superparamagnetic particles. Almost all the existing models assume free-standing particles dispersed in a nonbonding medium and predict an H_c higher than 1000 Oe for a moderate value of volume fraction of particles. In fact, the films with H_c more than 1000 Oe have been reported.²¹

In our case, however, the H_c of the granules are extremely small compared with results reported previously. For an assembly of noninteracting single domain particles, the predicted coercivity for coherent rotation is given by $H_c = 0.96 K/M_s$ for uniaxial anisotropy K . For α -Co this amounts to coercivity $H_c = 2700$ Oe. The low values of coercivity in as-sputtered films are believed to be the results of (1) the small anisotropy energy of fcc phase with (111) preferred orientation, mentioned before, and of (2) particle sizes much smaller than the single domain particle size, which is estimated to be 53 nm, leading to incoherent magnetization processes.

There are considerable differences of B_s and H_k between soft magnetic Co-N and Co-O based films. The B_s and H_k of Co-N based films are about 8 kG and 30 Oe, respectively. On the other hand, B_s and H_k of Co-O based films are 10 kG and 80 Oe, respectively. The difference in B_s is attributed to the difference of the ratio of Co/Al between Co-N and Co-O based alloys, and the difference of heat of formation

FIG. 8. Measured and calculated frequency characteristics of permeability for Co-Al-O granular films in the as-deposited state.

between Al-N and Al-O compounds. The reason for the difference in H_k may be due the difference of morphology of particles. Further investigation is required to give a full account of the phenomenon.

According to calculations based on the Landau-Lifshitz equation, as mentioned above, the frequency characteristics of the permeability in magnetic films are known to be improved by increases not only in ρ but also in the magnitudes of B_s and H_k . Large values of ρ , B_s , and H_k in soft magnetic Co-(Si,Al)-N and Co-Al-O films are advantageous to the μ - f characteristics. Figure 8 is a typical example of the μ - f characteristics of as-deposited $\text{Co}_{85}\text{Al}_{15}\text{-O}$ films. Despite the film thickness being nearly $2 \mu\text{m}$, the real part (μ') of permeability is flat up to 500 MHz and almost consistent with the calculations based on the experimental values for M_s , H_k , ρ , and d . However, the experimental result of the imaginary part (μ'') near 500 MHz is in poor agreement with the calculated one. One reason may be that the calculation neglects the effect of local eddy currents, which occur due to impedance associated with capacitance between metallic particles separated by insulating interparticles regions. An improvement of the theory, taking into account such effects, is now in progress. Another reason is the magnitude of the damping factor. In the case of the films shown in Fig. 7(b), their μ - f response is extremely poor. Also giant magnetoresistance characteristics have been observed;²² however, they will not be discussed further in this article.

Co-O based films are advantageous in having high B_s and ρ ; however, they show soft magnetic properties in a more limited composition range, compared with the results of Co-N based films. Consequently, the addition of other elements has been investigated for improving the soft magnetic properties of Co-O based films. Only Pd and Ni were found to improve the Co-O films, by causing them to be magnetically soft and also enhancing the anisotropy field.²³ Figure 9 shows typical magnetization hysteresis loops of as-deposited Co-Si-Pd-O films. Co-Si-O films do not show soft magnetic properties, as described above. Fairly soft magnetic properties and also a large H_k are observed in this system.

FIG. 9. Magnetic hysteresis loop of Co-Si-Pd-O granular films in the as-deposited state.

Another effective method for improving μ - f response is heat treatment. Recently, the μ - f characteristics at higher frequencies for Co-N based films were found to be improved by annealing at about 250 °C in a uniaxial magnetic field (UFA).²⁴ Annealing in magnetic field is also effective for Co-Pd-O based films with large H_k . The value of H_k decreases monotonically with increasing annealing temperature during rotational field annealing (RFA), and is almost 0 Oe near 250 °C. Therefore, films with any magnitude of H_k can be obtained by the combined use of RFA and UFA.

IV. CONCLUSIONS

We can point out that granular alloys with high electrical resistivities, saturation magnetizations, and anisotropy field can be made by rf reactive magnetron sputtering of Co-(Al or Si)-N and Co-Al-O films. Control of the metal volume fraction of Co/(Al or Si), the difference in the heat of formation between Co-(O or N) and Si-N, Al-(O or N) compounds, and the presence of fcc Co granules are essential for making such films. They represent a new type of high-frequency thin-film magnetic material, which may operate in the high-frequency range beyond 100 MHz with high μ' and

low μ'' . They are promising thin-film materials for applications such as high-frequency thin transformers and inductors, as well as thin-film heads for high-density magnetic recording.

Soft NiFe-Permalloy fibers and ultrasoft NiCo-based amorphous fibers, having a circular cross section with 30–40 μm in diameter, have been cast by melt extraction. The fibers have been driven by a sinusoidal current with 20 mA_{pp} constant amplitude and frequencies from 0.1 to 100 MHz. Both longitudinal and transverse giant magnetoimpedance effects have been observed in these fibers. The longitudinal GMI effect at 30 MHz was 60% in ultrasoft (NiCo)₇₀FeSiBMn fibers for a saturating field of about 7 kA/m. The same effect was found at 10 MHz frequency for Permalloy fibers for a larger saturating field (20 kA/m). The transverse GMI effect was smaller ($\approx 35\%$ for NiCo and $\approx 20\%$ for NiFe), and showed a maximum at low frequency (3 MHz). The magnetic field responses of the fibers are quadratic. An inverse effect of 10%–30% was observed for both types of fibers in longitudinal as well as in transverse field responses at high current frequency and low field strength. All of the observed effects could prove to be very useful for a new generation of high-sensitivity magnetic field sensors. © 1996 American Institute of Physics.

[S0021-8979(96)28908-3]

Recent reports of large magnetoinductive and magnetoimpedance effects in Unitika amorphous wires^{1–3} have prompted us to investigate whether soft and ultrasoft magnetic fibers show similar effects. These fibers have been obtained through melt extraction, a newly improved casting method,⁴ which uses a rotating wheel to extract solid fibers directly from the melt. The heat is removed along the contact line between the wheel and the melt, thus promoting frozen tensile stresses in the fiber, directed from the contact line towards the opposite surface, which is the last to solidify. This stress distribution produces a uniaxial anisotropy with a domain structure consisting mainly of domains perpendicular to the fiber length, and of longitudinal and, possibly, circumferential closure domains at the fiber surface. A simple model regards these fibers as assemblies of thin films, having in-plane anisotropy and fanning around the contact line. (A more exact geometrical description would be “thin wedges”.) Each film contains the contact line and all the fiber columns making the same angle to a reference horizontal axis.⁵ The anisotropy easy axis is parallel to the fiber for negative magnetostriction materials, and perpendicular for positive magnetostriction ones. Except for thin films, fibers are the magnetic elements with the lowest cross-sectional area, which makes them very suitable for sensing purposes. Radial solidification with respect to the extracting wheel, causing transverse stress and uniaxial anisotropy in the fiber, is the main feature of all fibers cast by melt extraction.

The domain structure of negative magnetostriction Co-

rich wires, showing an inner core with longitudinal domains and an outer shell with ring-like domains,³ is very different from the transverse domain distribution in NiCo and NiFe fibers. Their as-cast diameter is also different (125 μm wires vs 30–40 μm fibers). However, we measured almost identical GMI responses in near-zero, as well as in slightly negative and positive magnetostriction fibers.

Soft Permalloy fibers, having compositions of 80%wtNi/20%wtFe, 81Ni/19Fe, and 82Ni/18Fe, and positive, near-zero and negative magnetostriction,⁶ as well as ultrasoft amorphous 45Ni25Co6Fe9Si13B2Mn fibers, have been prepared and measured. The resistivity of NiFe fibers was about 30 $\mu\Omega\text{cm}$, while NiCo fibers showed a resistivity of 150 $\mu\Omega\text{cm}$. Samples of 80/20 Permalloy fibers have been vacuum annealed for several hours at 960 °C in order to relax the quenched-in stresses. Their resistivity increased to 60 $\mu\Omega\text{cm}$ and the fiber showed voids and unhomogeneities. All fibers were 20 mm long, quite homogeneous in properties and 30–40 μm in diameter. The measuring set-up consisted of a rf signal generator driving the fiber in series with a low value resistor. The output level of the generator was adjusted at each frequency so as to keep constant the voltage drop across the resistor. The current through the fiber was thus maintained at 20 mA_{pp} in amplitude. The GMI response is defined as:⁶

$$\Delta Z/Z \approx \Delta U/U = [U_f(H_{\text{sat}}) - U_f(H=0)]/U_f(H=0),$$

FIG. 1. The longitudinal and transverse GMI effects and the voltage drops across the amorphous NiCo fibers in zero and saturating fields vs the frequency of the driving current.

where H_{sat} is the longitudinal or transverse saturating field, applied using a pair of Helmholtz coils, and U_f is the voltage drop across the fiber.

Both longitudinal ($|\Delta Z/Z|_l$) and transverse ($|\Delta Z/Z|_t$) GMI effects are negative. The frequency behavior of these effects and of U_f in zero and saturating fields for NiCo amorphous fibers are shown in Fig. 1. The impedance of the fiber in zero field increases with increasing frequency up to a maximum at 30 MHz, then drops at higher frequency. When a 7 kA/m saturating longitudinal field is applied, U_f becomes almost frequency independent, as for a copper fiber. In transverse fields, the voltage drop across the fiber in "saturating" fields of about 20–30 kA/m increases with frequency. The maximum in $|\Delta Z/Z|_l$ is larger than 60% at 30 MHz, while the maximum in $|\Delta Z/Z|_t$ is 35% at 3 MHz, due to the different frequency behavior of $U_f(H_{sat})$. Figure 2 shows the fiber responses as functions of the strength of longitudinal and transverse fields. $|\Delta Z/Z|_l$ has larger sensitivity and saturates at higher field for higher frequency. The field variation of $|\Delta Z/Z|_t$ is not as steep, and shows a low field inverse effect, which reaches 10% at 1.5 MHz.

The GMI effects in Permalloy fibers are also negative. The longitudinal effect shows a maximum of 60% at 10 MHz, while the transverse effect has a maximum of about 20% at 1.5 MHz (Fig. 3). It is likely that we have not satu-

FIG. 2. The longitudinal and transverse magnetic field responses of the amorphous NiCo fibers for different frequencies of the driving current.

FIG. 3. The longitudinal and transverse GMI effects of several Permalloy fibers with different NiFe composition versus the frequency of the driving current.

rated the fiber in the transverse direction, where a maximum demagnetization occurs, using the Helmholtz coils. The GMI effect is the same for all three compositions of the NiFe alloy, even if the magnetostriction changes from positive to negative. The behavior of Permalloy fibers is almost identical to that of NiCo amorphous fibers, the only difference being the displacement toward lower frequency of the maximum GMI effect. In fact, the 20% value of $|\Delta Z/Z|_l$ appears at 1 MHz in case of amorphous fibers, and at only 220 kHz in case of Permalloy fibers. The latter case is more favorable when using fibers as magnetic field sensors.

Unlike the NiCo fibers, the NiFe fibers at saturation do not show a constant voltage drop as a function of frequency (Fig. 4). Both $U_f(H_{sat})$ and $U_f(H=0)$ increase with frequency, and the frequency variation of $\Delta Z/Z$ is determined by their different rates of variation. The increase of $U_f(f)$ with frequency was previously reported for Unitika amorphous wires.³ In our case, this increase may be simply caused by the unsaturated state of the fiber. Figures 3 and 4 also show the frequency behavior of the GMI effects and of the voltage drops for annealed Permalloy fibers, which are assumed to be stress free. The maximum in $|\Delta Z/Z|_l$ is only slightly lower than those of as-cast fibers. However, the maximum in $|\Delta Z/Z|_t$ is half of the original value and both maxima are displaced toward higher frequency. The variation

FIG. 4. The voltage drops across the as-cast and annealed 80Ni/20Fe Permalloy fibers in zero and saturating fields vs the frequency of the driving current.

FIG. 5. The longitudinal magnetic field responses of several Permalloy fibers with different NiFe composition.

in voltage drops remains unaltered, and only the magnitude of U_f is larger due to the increase in fiber resistivity after annealing.

The longitudinal GMI responses of as-cast Permalloy fibers show that the saturating field is considerably higher than that of amorphous fibers (Fig. 5). However, the annealed 80Ni/20Fe fibers seem to be softer than the as-cast fibers with the same composition. The inverse effect is present for all compositions, being the largest for 82Ni/18Fe. The fact that this effect disappears from the response of the stress-free annealed fiber, suggests that the inverse effect may be related to the magnitude of the quenched-in stresses. The transverse GMI responses of Permalloy fibers show little sensitivity and quite large saturating fields (50 kA/m).

A surprising similarity in the magnitude and frequency behavior of longitudinal and transverse GMI effects was found for ultra soft NiCo amorphous fibers and for soft NiFe fibers with slightly negative, near-zero and positive magnetostriction. The longitudinal effect is quite similar to that reported for Unitika amorphous wires, even if fibers are very different from wires in terms of geometry, composition, and quenched-in stress distribution. It seems that GMI is a general effect, not limited to a very particular type of magnetic sample. Whatever the origin of GMI, soft and ultra soft magnetic fibers have the potential to be used as sensing elements for a new generation of magnetic field sensors. Depending on the application, the sensitivity of the fiber can be changed by adjusting the frequency of the driving current such as to obtain optimized sensing devices.

Giant magneto-impedance effects in Metglas 2705M

R. L. Sommer^{a)} and C. L. Chien

Department of Physics and Astronomy, The Johns Hopkins University, Baltimore, Maryland 21218

Giant magneto-impedance (GMI) results for Metglas 2705M have been studied in two measuring geometries in several field annealed samples. A rich variety of peak features in GMI, all within a small field range, have been observed. The various features in the GMI are discussed in terms of magnetic susceptibility and microstructural properties of the amorphous ribbon. © 1996 American Institute of Physics. [S0021-8979(96)29008-8]

The observation of giant magneto-impedance (GMI) in amorphous alloys with negligible magnetostriction¹⁻³ has attracted a great deal of attention for fundamental and technological interest. The origin of the effect appears to be the field dependence of the effective differential susceptibility of the soft amorphous materials. The GMI effect is better understood in the case of wires,² but many aspects remain to be unraveled in the case of ribbons. Very recently,⁴ a rich variety of peak features in GMI within a small field range have been observed in suitably annealed amorphous samples of CoFeSiB alloy. The aspects of annealing and measuring geometries in the GMI effects in commercial amorphous ribbons remain to be resolved. In this work, the GMI effects in commercial Metglas 2705M (nominal composition $\text{Co}_{69}\text{Fe}_4\text{Ni}_1\text{Mo}_2\text{B}_{12}\text{Si}_{12}$) ribbons have been studied in two geometries (longitudinal and transverse) for several field-annealed samples with frequencies up to 100 kHz and currents in the range $0.1 < I < 20$ mA. The rich variety of GMI spectra observed can be accounted for by using a simple model.

The samples were cut from the middle sections of a commercial Metglas 2705M ribbon (nominal thickness of 20 μm and resistivity of about 150 $\mu\Omega\text{cm}$) with dimensions of about 10 mm \times 1 mm. The leads were made by using In solder and the GMI was detected via a two-channel lock-in amplifier. For the four probe measurements, a low-noise current source provided sinusoidal currents between 0.1 and 20 mA. The probe current frequency range used in these experiments was $0.1 \text{ Hz} \leq f \leq 100 \text{ kHz}$. During all data acquisition, the quasi-static dc field was swept between -150 and $+150$ Oe and back, although only the data of the increasing field part are displayed. The GMI results are expressed as $\Delta Z/Z_{dc} = [Z(H) - Z(5 \text{ kOe})]/R_{dc}$, $\Delta R/R_{dc} = [R(H) - R(5 \text{ kOe})]/R_{dc}$, or $\Delta X/R_{dc} = [X(H) - X(5 \text{ kOe})]/R_{dc}$, where Z is the impedance, R the resistance, X the reactance, and R_{dc} the dc resistance. Similar to those in Ref. 4, the samples were subjected to four different annealing geometries: as-cast (AC); annealed in zero field (ZFA); longitudinally annealed (LA) with a 2 kOe field oriented parallel to the long direction of the sample; transversely annealed (TA) with a transverse field of 2 kOe. All annealing took place at $T_A = 300^\circ\text{C}$ for 15 min in an Ar atmosphere. Two geometries for the measurement were adopted. In the longitudinal magneto-impedance (LMI) measurements, the probe current and the external dc

field were applied along the long direction of the sample. In the transverse magneto-impedance (TMI) measurements, the probe current was parallel to the long direction of the sample but the field was applied perpendicular to the current and remained in the ribbon plane.

In Fig. 1, the LMI measurements at frequency $f = 100$ kHz under a 20 mA peak value for the probe current for the samples subjected to four different field annealing geometries are shown. The as-cast sample exhibits a 15% MI effect [see Fig. 1(a)] and a width of about 10 Oe with little structure. Annealing in zero field [see Fig. 1(b)] decreases somewhat the effect size and the width. Substantial changes occur after field annealing, which causes significantly larger widths of about 30 Oe. The LA sample [see Fig. 1(c)] shows a much smaller effect, whereas the TA sample [see Fig. 1(d)] gives the largest effect of the four samples with a more interesting structure consisting of four peaks. The intricate peak structure of the TA sample is better displayed in the insets of Fig. 2 for both reactance (ΔX) and resistance (ΔR), where the two shoulder peaks (a, d) and the two central peaks (b, c) are labeled.

In Fig. 2, the magnitudes of the four peaks of ΔR and ΔX are plotted as a function of frequency. At the same frequency, the effect size of ΔX is larger than that of ΔR . Between the shoulder and the central peaks, there is a very different frequency dependence in both resistance and reactance, indicating that they are of different origins. Depending on the relative size of the sample thickness (t) and the skin depth (δ_m), a frequency dependence of approximately f or

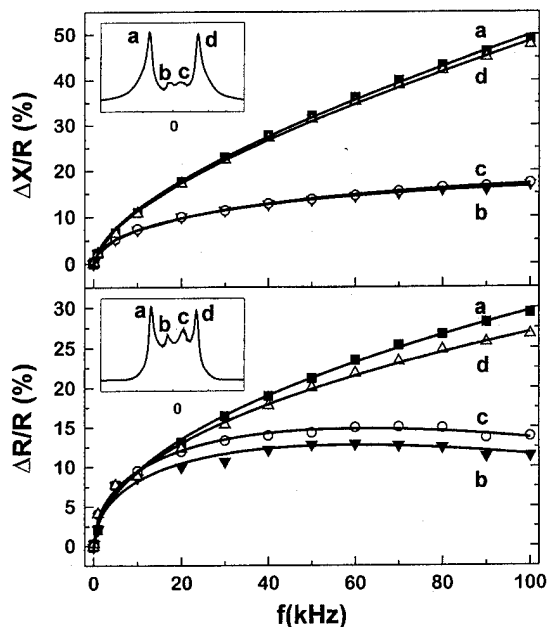

FIG. 2. Intensities of various peaks (*a*, *b*, *c*, and *d*) vs frequency in longitudinal magneto-impedance (LMI) of a Metglas 2705M sample annealed in a transverse field. The insets show the reactance (*X*) and resistance (*R*) vs *H* curves.

$f^{1/2}$ may be realized.² Since δ_m depends on the permeability value, which is not known beforehand, the applicable regime cannot be ascertained *a priori*. We find the experimental results can be well described by using $pf + qf^{1/2}$ with two parameters *p* and *q*. In most frequency ranges, particularly at high frequencies, the $f^{1/2}$ dependence dominates as it should. However, the *p* and *q* values needed to fit shoulder and center peaks are different.

In Fig. 3(a), the transverse magneto-impedance measurements (TMI) for the TA sample are shown. TMI is a new measuring geometry; previous studies failed to have observed a substantial effect due to the lack of higher field measurements.^{1,3} Comparing the results of TMI and LMI of the TA sample, the resolution of the TMI is clearly inferior; the TMI exhibits a broad plateau without discernible peak structure. It should be noted that the principal difference between LMI and TMI is that the width of TMI is about ten times larger than that for LMI.

The observed results of different measuring geometries (LMI and TMI) and different field annealing can be understood by recognizing the appropriate components of the susceptibility, the roles of anisotropy and field annealing, and the demagnetizing factor due to the ribbon sample shape. First of all, since the probe current is always along the ribbon direction, the field H_{ac} generated by the probe current is always perpendicular to the ribbon direction. Consequently, in the longitudinal GMI (LMI), where *H* is along the ribbon direction, it is the transverse susceptibility (χ_T) that contributes. In the transverse GMI (TMI), where *H* is perpendicular to the ribbon direction, it is the longitudinal susceptibility (χ_L) that contributes.

For amorphous alloys with nearly zero magnetostriction, it is well known that field annealing can induce an anisotropy.

FIG. 3. (a) Transverse magneto-impedance (TMI) at 100 kHz and 20 mA of a Metglas 2705M sample annealed in a transverse field. The $\Delta R/R$ and $\Delta X/R$ results are shown. (b) LMI and TMI as a function of the reduced magnetization (M/M_s).

This is due to the random nature of the magnetic anisotropy in the as-cast materials and the absence of appreciable magnetoelastic contribution to the effective anisotropy. Annealing with the longitudinal field induces an anisotropy in the longitudinal direction, and transverse annealing induces an transverse anisotropy. It is also well known that magnetic annealing greatly enhances the permeability, which is the underlying mechanism for the GMI effects.

We first discuss the LMI results, where the *H* field is applied along the ribbon direction. In the as-cast sample, the absence of peak structure suggests negligible anisotropy, which is somewhat different from those found in other amorphous materials.⁵ As a result, there are only small differences between the LMI spectra of the as-cast and the zero field annealed samples. In the LA sample, the average magnetization and the induced anisotropy axis are along the ribbon direction, which is perpendicular to H_{ac} . The small magnitude of H_{ac} is incapable of appreciably altering the magnetization along the ribbon direction, hence a very small effect, as shown in Fig. 1(c). In the TA sample, the easy axis, described by the effective anisotropy field H_K , is perpendicular to the ribbon direction and parallel to the H_{ac} produced by the probe current. This results in a much larger effect, as shown in Figs. 1(d) and 2. The peak structure (labeled *a*, *b*, *c*, and *d* in the inset of Fig. 2) is due to two different magnetization processes excited by the probe current. The shoulder peaks, or the outer peaks (labeled *a* and *d* in the inset of Fig. 2), located at ± 6.5 Oe, as shown in Fig. 1(d), are caused by the rotation of the magnetization against the anisotropy field. The peak location of 6.5 Oe marks the value of $H_i = H - 4\pi D_L M \approx H_K$, and corresponds to the peak observed in the transverse differential susceptibility.^{6,7} The cen-

tral peaks, or the inner peaks (labeled *b* and *c* in Fig. 2), as shown in Fig. 1(d), are probably due to the movement of a transverse domain wall (DW) structure. These domain walls would move under the combined action of H_{ac} and H fields for $H < H_K$. Eventually a coercive field for such a domain wall motion can be defined where the maximum in the susceptibility associated with the DW motion occurs.

For the TMI results, the relevant susceptibility now is the longitudinal susceptibility (χ_L). However, the demagnetization effects, which are negligible in the LMI case, now become important. As a result, the relevant longitudinal susceptibility has an *apparent* value of

$$\frac{\chi_L^{app}}{1 + 4\pi \cdot D_T \chi_L},$$

which is χ_L corrected for demagnetization effects and D_T is the demagnetization factor in the transverse direction. Because of the large value of χ_L , hence $4\pi \cdot D_T \gg 1$ and the apparent susceptibility is given by $\chi_L^{app} \approx 1/4\pi \cdot D_T$, i.e., the longitudinal susceptibility is *clamped* by the demagnetization factor, not reflecting its own field dependence. Consequently, the TMI results exhibit a plateau with no resolvable peak structure, as shown in Fig. 3(a). Furthermore, by the same token, the internal field $H_i = H - 4\pi \cdot D_T M$ is also very different from the applied field H . Hence, the TMI effects occur over a much wider field values than those of LMI, as shown in Fig. 3(a).

For the reasons given above, one cannot compare the TMI and LMI within the same field range, which disregards the effects of the demagnetization factor. Instead, the TMI and LMI results should be compared at the same magnetization value. This is shown in Fig. 3(b), where we show the LMI and TMI results at 100 kHz and 20 mA. While the LMI result shows the intricate peak structure, the TMI result is essentially featureless, because the relevant susceptibility has been limited by the demagnetization factor. The main GMI effect, in both LMI and TMI, occurs in *different* field ranges but in the *same* magnetization range. Under a sufficiently large external field, which saturates the magnetization, there is no GMI effect. The "clamping" effect of the demagnetization factor on the TMI is clearly shown in Fig. 3(b). This comparison also vividly illustrates that the LMI in the TA sample provides most information concerning the GMI effects.

In Fig. 4, we show the LMI vs H curves for the TA sample at selected frequencies from 1 Hz to 100 kHz. At very low frequencies [e.g., at 1 Hz as shown in Fig. 4(a)], one essentially measures the dc resistance curve. For this ferromagnetic alloy, there is small (0.02%) and negative anisotropic magnetoresistance (AMR) as expected. Even at a low frequency of 100 Hz [Fig. 4(b)], the larger and positive GMI effect (with a double-peak structure) has overridden the smaller and negative AMR effect. When the frequency is further increased, the magnitude of the GMI effects increases, and the structure becomes more resolved. For inter-

FIG. 4. Longitudinal magneto-impedance (LMI) at 20 mA of a Metglas 2705M sample annealed in a transverse field and measured at various frequencies: (a) 1 Hz, (b) 100 Hz, (c) 1 kHz, (d) 10 kHz, (e) 25 kHz, and (f) 100 kHz.

mediate frequencies [e.g., Figs. 4(b) and 4(c)], the inner peaks are larger than the outer ones. For higher frequencies, the outer peaks clearly dominate. One also observes that as the frequency is increased, the locations of the peaks shift to higher values. This is a general property of the transverse susceptibility.⁷ The effect of the magnitude of the probe current on the LMI at 100 kHz has also been studied. It is observed that the inner peaks are better defined only when the probe current has exceeded 5 mA, beyond which the spectra appear to be essentially independent of the probe current.

In summary, a rich variety of GMI results have been observed in Metglas 2705M, a commercially available amorphous ribbon. We show that transverse field annealing is crucial in bringing out the detailed features of the GMI spectra. The TMI is hampered by the demagnetization effects, whereas the LMI reveals the intricate peak structure. We show that rotation against the anisotropy field and domain wall motion are the two main factors controlling the GMI effects.

Barkhausen noise in FeCoB amorphous alloys (abstract)

G. Durin and G. Bertotti

IEN Galileo Ferraris, GNSM and INFM, C.so Massimo d'Azeglio 42, 10125 Torino, Italy

In recent years, the Barkhausen effect has been indicated as a promising tool to investigate and verify the ideas about the self-organization of physical complex systems displaying power law distributions and $1/f$ noise. When measured at low magnetization rates, the Barkhausen signal displays $1/f^\alpha$ -type spectra (with $\alpha=1.5\div 2$) and power law distributions of duration and size of the Barkhausen jumps.¹ These experimental data are quite well described by the model of Alessandro *et al.*² which is based on a stochastic description of the domain wall dynamics over a pinning field with brownian properties. Yet, this model always predicts a $1/f^2$ spectrum, and, at the moment, it is not clear if it can take into account possible effects of self-organization of the magnetization process. In order to improve the power of the model and clarify this problem, we have performed a thorough investigation of the noise spectra and the amplitude distributions of a wide set of FeCoB amorphous alloys. The stationary amplitude distribution of the signal is very well fitted by the gamma distribution² $P(\nu) = \nu^{c-1} \exp(-\nu)/\Gamma(c)$, where ν is proportional to the domain wall velocity, and c is a dimensionless parameter. As predicted in Ref. 2, this parameter is found to have a parabolic dependence on the magnetization rate. In particular, the linear coefficient is related to the amplitude of the fluctuations of the pinning field, a parameter which can be measured directly from the power spectra. In all measured cases, the power spectra show α exponents less than 2, and thus poorly fitted by the model. Actually, the absolute value of the high frequency spectral density is not consistent with the c parameter determined from the amplitude distribution data. This discrepancy requires to introduce effects not taken into account in the model, as the propagation of the jumps along the domain wall.³ This highly enhances the fit of the data and indicates effects of propagation on the scale of a few millimeters. These results are analyzed in terms of new descriptions of the statistical properties of the pinning field based on fractional brownian processes. © 1996 American Institute of Physics. In order to study the influence of the nanocrystalline microstructure on the magnetic properties of pure nanocrystalline metals, *in situ* magnetic measurements of high-purity nanocrystalline nickel, prepared by a gas-condensation technique with subsequent compaction at various pressures have been performed. The approach to ferromagnetic saturation indicates free volumes in the nanocrystalline system of the size of individual missing crystallites as well as internal stresses. While the saturation polarization of the nanocrystalline Ni samples appears to be unchanged compared to coarse-grained Ni the coercive field and magnetic domains are strongly influenced by the nanocrystalline structure. The shape of the domains with sizes of 10–200 μm much larger than the crystallite size depends on the annealing state of the specimen. The initial coercive field increases with the compaction pressure during preparation. Upon annealing it further increases to a maximum value at $T_a = 500^\circ\text{C}$ and decreases at higher annealing temperatures. Additionally, the effect of oxygen located in the grain boundaries has been studied. © 1996 American Institute of Physics. [S0021-8979(96)29108-4]

I. INTRODUCTION

The magnetic properties of nanocrystalline materials were investigated intensively over the last few years due to a high potential for future technical applications. In order to study the influence of the microstructure on the magnetic properties of nanocrystalline materials, nanocrystalline Ni as a model system of a pure nanocrystalline ferromagnetic metal has been investigated recently by several groups.^{1–4} Because impurities such as oxygen contamination play an important role in the magnetic properties of these ultrafine grained materials, *in situ* magnetic measurements have been performed in the present work by exclusively handling the specimens in vacuum.

II. PREPARATION AND CHARACTERIZATION

Nanocrystalline Ni samples have been produced by the inert gas-condensation technique⁵ with subsequent compaction at various pressures (0.5–2 GPa). The mass density of the nanocrystalline samples was about 80% the bulk value. *In situ* nuclear reaction analysis for the determination of the oxygen contents in specimens handled in vacuum or after exposure to air yield 0.5 at. % or 6 at. % of oxygen, respectively. From *in situ* x-ray line broadening a mean crystallite size of 10 nm and internal strains of $\langle e^2 \rangle^{1/2} = 0.4\text{--}0.9\%$ are deduced. This average crystallite size is consistent with the observation by transmission electron microscopy. Upon isochronal annealing (1 h) the mean crystallite size slowly increases with increasing annealing temperature with strong crystallite growth starting at an annealing temperature of 300 $^\circ\text{C}$. The internal strains decrease to 50% of the initial value upon annealing at 100 $^\circ\text{C}$.

III. APPROACH TO FERROMAGNETIC SATURATION AND SPONTANEOUS POLARIZATION

Measurements of the magnetic moment m as a function of temperature and applied field were performed with a superconducting quantum interference device (SQUID) magnetometer at temperatures between 5 and 320 K and in external fields $-7\text{ T} < \mu_0 H_{\text{ex}} < 7\text{ T}$.

The analysis of the approach to ferromagnetic saturation then carried out is based on the magnetoelastic coupling between internal stresses caused by defects and the spontaneous magnetization J_s . These measurements of the approach to ferromagnetic saturation therefore yield information on the geometry, the size, and the concentration of the defects. The high-field polarization can be described in general as

$$J(T, \mu_0 H) = J_s(T) - \sum_{i=1}^n a_i (\mu_0 H)^{p_i}, \quad (1)$$

where $J_s(T)$ describes the spontaneous polarization at a constant temperature T and p_i the exponents of the field terms with amplitudes a_i . Spin inhomogeneities with a typical field dependence as $p = -\frac{1}{2}$ are characteristic for point defects⁶ or nonmagnetic inclusions,^{7,8} whereas the term with $p = 1$ describes dislocation dipoles^{9–11} and the term with $p = 2$ is typical for separate edge dislocations. At higher temperatures the thermal energy causes an additional field dependence as $p = -\frac{1}{2}$, which is known as para effect.¹²

In situ measurements of the approach to ferromagnetic saturation in high-purity nanocrystalline Ni indicate that the field dependence of the polarization of the as-prepared specimens can be well described by

FIG. 1. Polarization J vs $1/(\mu_0 H)^{1/2}$ of high-purity nanocrystalline Ni according to Eq. (2). The deviation from a linear behavior at high external fields is due to the para effect.

$$J(\mu_0 H) = J_s - a_{-1/2} \frac{1}{\sqrt{\mu_0 H}} \quad (2)$$

at high fields, above $\mu_0 H_{ex} = 0.9$ T (see Fig. 1) with $a_{-1/2}$ being constant. This field dependence may result from stress fields due to point defects or the magnetostatic contribution of spherical nonmagnetic inclusions, such as nanovoids. This only holds if the defect radii are smaller than the exchange length ℓ_{ex} and the distances between the defects are larger than ℓ_{ex} . Therefore the upper limit of the defect density N_{max} is given by

$$N_{max} = \frac{3}{4\pi} \frac{1}{\ell_{ex}^3} \quad (3)$$

For nonmagnetic inclusions such as nanovoids the microstructural constant $a_{-1/2}$ is given by^{7,8}

$$a_{-1/2} = \frac{\sqrt{2} \pi^2 J_s^2}{27 \sqrt{\mu_0 A_{ex}}} r_0^4 N, \quad (4)$$

where r_0 describes the radius and N the density of the spherical nonmagnetic inclusions. Taking the maximum density of defects [see Eq. (3)], we may estimate a minimum radius r_0 applying Eq. (4). With J_s and $a_{-1/2}$ derived by fitting Eq. (2) to the experimental data and with A_{ex} of bulk Ni, we obtain a minimum radius of the voids of $r_0 = 6.5$ nm which is about the size of individual missing crystallites. Smaller voids with $r_0 = 2.1$ nm in nanocrystalline Fe were reported by Hirscher *et al.*, applying the same technique of analyzing the approach to ferromagnetic saturation.¹³

Upon annealing for 1 h at 100 °C, the field dependence significantly changes and an additional field term $1/(\mu_0 H_{ex})^2$ is required for a good fit to describe the approach to ferromagnetic saturation. This field term may be ascribed to long-range internal stress fields¹⁴ with

$$a_{-2} = \frac{3}{5} \frac{\mu_0^2 \lambda_s^2}{J_s} \sigma_i^2. \quad (5)$$

With the constant a_{-2} and the magnetization J_s derived by fitting Eq. (1) to the experimental data we obtain the value of

FIG. 2. Variation of the saturation magnetization M_0 upon isochronal annealing ($t_a = 1$ h) without (○) or after air exposure of the samples (?). The value of bulk Ni is indicated by a dashed line (---).

the internal stresses $\sqrt{\sigma_i^2} \approx 0.85$ G Pa being of the same order of magnitude as the internal stresses which can be derived from the strains detected by x-ray line broadening.

The temperature variation of the spontaneous magnetization $J_s(T)$ was determined analyzing the approach to ferromagnetic saturation [see Eq. (1)] at various temperatures. Extrapolation of $J_s(T)$ to zero temperature yields the saturation polarization J_0 . Figure 2 shows the variation of the saturation polarization J_0 with increasing annealing temperature T_a for high-purity nanocrystalline Ni as well as of nanocrystalline Ni with 6 at. % oxygen in the grain boundaries after air exposure. Whereas the saturation polarization of the high-purity n-Ni samples is unchanged compared to bulk Ni, oxygen contamination of the samples significantly reduces J_0 . No Ni oxide was observed by x-ray diffraction analysis in the specimens containing 6 at. % of oxygen.

IV. DOMAIN STRUCTURE AND COERCIVE FIELD

The magnetic domain structure of nanocrystalline Ni samples (n-Ni) was studied by means of magneto-optic Kerr microscopy. A fine and irregular domain structure with a mean domain size of 12 μm was found in the as-prepared samples indicating a strong decrease of the effective crystal anisotropy which can be explained by the random anisotropy model¹⁵ if the crystallite size is smaller than the exchange length ℓ_{ex} . After annealing the specimens for 1 h at 100 °C, elongated domain structures of a mean width of 30 μm appeared (see Fig. 3), which is typical for a material with an anisotropy dominated by internal stresses. This change in the magnetic domain structure can be explained by a transition from a system with very small crystal anisotropy to that with dominating magnetoelastic anisotropy due to the long-range internal stress fields induced upon annealing (analogous to the observations of the approach to ferromagnetic saturation).

The magneto-optic Kerr studies at various external magnetic fields along with *in situ* measurements of the coercive field H_c , indicate that the magnetization process in nanocrystalline Ni is dominated by domain wall movements. The coercive field in n-Ni of some 10 mT, much higher than in bulk Ni (0.01 mT) has been measured, indicating that the

FIG. 3. Elongated domains in nanocrystalline Ni after annealing at 100 °C for 1 h.

magnetization process is impeded by pinning of the domain walls in the nanocrystalline structure. In a simple model of domain wall movement in an uniaxial sinusoidal stress field, the temperature variation of the coercive field can be written as^{16,17}

$$\mu_0 H_c \approx \frac{\lambda_s \Delta \sigma}{M_s} \left(\frac{\lambda}{\delta_B} \right), \quad (6)$$

where λ_s , M_s , and $\Delta \sigma$ denote the isotropic magnetostriction constant, the spontaneous magnetization, and the amplitude of the stress field, respectively, if the wavelength of the stress field λ is smaller than the domain wall width δ_B . Fitting Eq. (6) to the experimental data and assuming a wavelength λ of the stress field equal to the mean crystallite size (10 nm) in the as-prepared nanocrystalline samples, we obtain the amplitude of the stress field of $\Delta \sigma = 0.32$ GPa or 1 GPa for compaction during preparation at 1 GPa or 2 GPa, respectively. These values are of the same order of magnitude as the internal stresses obtained from x-ray diffraction line broadening as well as from the analysis of the approach to ferromagnetic saturation.

V. CONCLUSION

Internal stresses are found to strongly influence the magnetic properties of compaction prepared nanocrystalline nickel. The stress fields in the nanocrystalline specimens

have been detected by x-ray line broadening. The value of these stresses increases with increasing compaction pressure during preparation. However, by analyzing the approach to ferromagnetic saturation the stress field can only be detected after annealing of the samples. Additionally, the magnetic domain structure changes upon annealing from initially diffuse domains, typical for a small effective crystal anisotropy, to elongated domains which can be ascribed to dominating magnetoelastic anisotropy in the annealed state. This change upon annealing can be explained by structural relaxation increasing the wavelength of the stress field. The temperature variation of the coercive field in the nanocrystalline Ni samples can be described by domain wall movement in an uniaxial stress field of the same order as determined by x-ray diffraction and by analyzing the approach to ferromagnetic saturation.

Zero-field and in-field small-angle neutron scattering measurements over a wide Q range are presented for the Fe₉₁Zr₉ metallic glass in the 10–290 K range. Two transitions observed at 210 K and around 60 K are related to Tc and reentrant transition temperature, respectively. The spectra ($0.003 \text{ \AA}^{-1} < Q < 0.5 \text{ \AA}^{-1}$) reveal the existence of an important contribution at the lowest Q values and at least two humps in the entire curves. The application of the magnetic field results in an anisotropic signal, and a global decrease of intensity. The magnetic field drastically reduces $I(Q)$ in the region for $Q < 0.04 \text{ \AA}^{-1}$, but not so strongly at larger Q values (even at $H = 4$ T), becoming more evident a remaining hump. Its origin can so far be uniquely explained by the models dealing with the existence of clusters embedded in a ferromagnetic matrix. © 1996 American Institute of Physics. [S0021-8979(96)29208-0]

I. INTRODUCTION

Fe_xZr_{100-x} glasses ($x \approx 90$) have attracted considerable attention because of their striking magnetic properties. The magnetic phase diagram exhibits reentrant spin glass (RSG), ferromagnetic (FM), and paramagnetic (PM) regimes depending on the composition and temperature.¹ The existing explanations are controversial and based on diverse physical views. On the one hand, some authors suggest a mixed phase with ferromagnetic order in the z direction coexisting with spin glass in xy directions, i.e., transverse spin freezing (TSF).¹ On the other, there are approaches dealing with magnetic clusters embedded in a matrix, being the coupling inside the cluster antiferromagnetic (AFM-FM)² and ferromagnetic (FM-FM).³ The basic origin of the clusters is different for the latter two, caused by chemical and density fluctuations in the structure, respectively. In addition, a superparamagnetic behavior has been put forward to explain magnetization⁴ and χ_{ac} .⁵ During the last few years, the FM-FM model has been supported by an increasing evidence of ferromagnetic resonance (FMR),⁶ bulk magnetization (BM),³ and Mössbauer (MS) results.³ However, Ren and Ryan⁷ have explained recently some of the existing results, using a wide compositional range, in terms of the TSF model.

It is clear that a direct experimental evidence of the existence or not of the clusters in these alloys is of paramount interest. SANS technique is a tool for such a purpose and in fact several studies have already been carried out using Fe-Zr alloys by Rhyne *et al.*,⁸ who pointed out the inhomogeneous magnetism in the alloys. Recently, Mergia *et al.*⁹ have extended the study using in-field SANS, and showing dependencies of $I(Q)$ on the field. The conclusions of these

studies are somewhat indefinite and an even more complete study should be desirable. Partial uncertainty came from the fact that the SANS for these alloys may include several contributions, some of which could be manifested especially in the very low Q region and then are blurred if an insufficient large Q range is covered.

As a consequence of these considerations, we have undertaken an intensive study of the SANS on Fe₉₁Zr₉, employing a range extended to lower Q values and under magnetic fields up to 4 T. In this communication, the initial SANS results are presented. Use of a wide Q range will help to ascertain any hidden contribution while the application of magnetic fields will affect the contributions to SANS intensity coming from magnetic origin.

II. EXPERIMENT

Ribbons 1.5 mm wide and 0.02 mm thick were cast by melt spinning under argon atmosphere. X-ray diffraction showed no crystallinity in both ribbon faces. SANS between 15 and 300 K was performed in LOQ instrument ($0.006 \text{ \AA}^{-1} < Q < 0.2 \text{ \AA}^{-1}$) in the Rutherford-Appleton Laboratory, and in a SANS diffractometer in Risoe ($0.003 \text{ \AA}^{-1} < Q < 0.5 \text{ \AA}^{-1}$). Samples were wrapped in a rectangular shape Al foil, which was placed vertically. In Risoe, fields up to 4 T were applied vertically along the longitudinal ribbon direction, while in LOQ, a horizontal field (0.26 T) was used. Usual corrections were performed.¹⁰

III. RESULTS AND DISCUSSION

Figure 1 shows $I(Q)$ behavior (in Log-Log scale) in $H = 0$ T field for temperatures in the three magnetic phases:

FIG. 1. $I(Q)$ in Log-Log scale for sets of data obtained in LOQ and Risoe instruments. LOQ data have been normalized to the Risoe data.

RSG (15 K), FM (150 K), and PM (290 K), for LOQ and Risoe runs. It is clear that both sets show the same results, though the Risoe data extend down to very low Q values. In fact, in these latter, an intensity increase is observed. The data in this Q region must be considered for any fitting evaluation, and it is expected that it will alter the previous SANS results.^{8,9} Moreover, it is important to note that the $I(Q)$ in the PM regime is unusually large, which could be a sign of persistence of inhomogeneities above T_c (clustering or short-range magnetic correlations). It is also interesting that in the FM and RSG regimes, an enhancement of at least two humps is building up centered around 0.004 and 0.05 \AA^{-1} . In Figure 2, the $I(T, Q=\text{fixed})$ behavior is shown to check for any transitions. As observed in Refs. 8 and 9, there is a cusp around T_c (210 K for $\text{Fe}_{91}\text{Zr}_9$) in agreement with BM, MS,

FIG. 2. $I(Q=\text{fixed}, T)$ for two Q values in zero-field configuration.

FIG. 3. $I(Q)^{-1}$ vs Q^2 for a few characteristic temperatures.

etc. Another feature is the steady increase of signal, significantly when $T < 80$ K, towards the RSG state. At the lowest Q value, it is detected in a broad maximum close to T_{RSG} (around 60 K).

SANS from a normal ferromagnet is described by a Lorentzian (L1), whereas for the systems with random anisotropy, a Lorentzian + (Lorentzian)² (L2) behavior of $I(Q)$ has been proposed.¹¹ Plots to check the L1 behavior are too far to be linear in the studied Q range (see Fig. 3). So, a pure ferromagnetic behavior must be ruled out.⁸ L2 fittings do not account for the results because more than two contributions could be extracted from the curves, as seen in Fig. 1. Then, it would be valuable to include an extra term for the fittings, as in the following expression:

$$I(Q) = \frac{A}{Q^2 + \kappa_1^2} + \frac{B}{(Q^2 + \kappa_2^2)^2} + \frac{C}{(Q^2 + \kappa_3^2)^2}. \quad (1)$$

Equation (1) has been used to fit $I(Q)$ in the overall Q range. If any of these contributions is negligible, the corresponding coefficient (A , B , or C) must tend to zero. The calculations reveal that Eq. (1) yields the lowest χ^2 . The variation of the fitted coefficients and correlation lengths ($\zeta_1 = 1/\kappa_1$, $\zeta_2 = 1/\kappa_2$, and $\zeta_3 = 1/\kappa_3$) are presented in Fig. 4. The main contribution to $I(Q)$ stems from the Lorentzian term, which is expected to include magnetic scattering from the ferromagnetic matrix. In addition, the SANS signal should also contain an underlying structural scattering and this contribution is still large above T_c . Parameter ζ_1 shows an enhancement in the FM region. Regarding to the B contribution, it is more important at $T < T_{\text{RSG}}$, revealing the existence of the RSG state. This term is small for $T > T_{\text{RSG}}$, whereas the correlation length increases in the ferromagnetic region, as corresponds to the long-range alignment of the moments. The third contribution is small and rather constant, but fading away for $T > T_c$. To derive more information, it is helpful to deal with the magnetic scattering only. For this, the PM signal has been subtracted from the FM and RSG intensities. $I(\text{RSG}) - I(\text{PM})$ leads to an entirely positive magnetic contribution for all Q values, but $I(\text{FM}) - I(\text{PM})$ results in negative values around the central Q values. This is important as it is witnessing the large PM intensity. Preliminary calculations show that in this case Eq. (1) still improves the quality of fittings. Though all the scattering coefficients decrease with respect to those in Fig. 4, this effect is especially intense in the Lorentzian coefficient (ten times smaller), confirming that this term contains a structural contribution. On the other hand, the variations of the fitting parameters resemble those in Fig. 4.

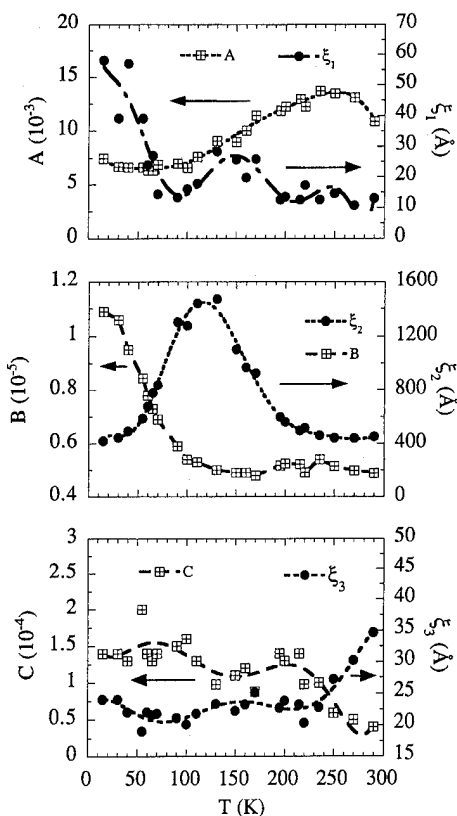

FIG. 4. Thermal dependence of the fit parameters in the expression (1).

When a magnetic field is applied, the contour intensity patterns become anisotropic due to the moment alignment along the field direction. A low 0.26 T field is sufficient to origin these anisotropic contours and result in a decrease of the entire intensity. Larger fields result in a slightly further decrease of the intensity. In Fig. 5, the comparison of zero- and in-field measurements for the three regimes is presented. The most important effect is observed in the lower Q values, being more pronounced in the RSG regime. While for 290 K curves the signals coincide for $Q > 0.04 \text{ \AA}^{-1}$, this is not the case in the magnetic regimes. An enhancement of the humps around 0.04 \AA^{-1} is clear at lower temperatures. These results could be interpreted as the alignment of the matrix magnetic moments, destroying the spin-glass state, and then reducing the intensity in the lower Q range. In addition, this alignment is also detected in the PM regime. However, the magnetic field does not affect the central hump of the curves in the three temperatures. Then, this remaining hump needs the existence of SANS centers to be understood, and not influenced by magnetic fields of such magnitude. The closest physical picture to explain this is that related to the existence of clusters in these alloys.

Although these results and discussions must be considered as preliminary, signs of the existence of ferromagnetic clusters have been detected in the wide Q -range spectra, which are encouraging a deeper analysis. Indeed, the key point is to separate the magnetic and structural contributions; two ways are open for such a purpose: an extensive fitting

FIG. 5. Comparison between zero-field and in-field (4 T) SANS intensity for a given temperature in the PM, FM, and RSG states.

procedure for the subtracted FM-PM and RSG-PM spectra, considering more temperatures and new theoretical approaches, and a complete evaluation of the anisotropic signal in the in-field experiments. Both studies are already being carried out.

The structure, soft magnetic properties, magnetostriction, grain size and volume fraction of the residual amorphous phase have been studied for an amorphous $\text{Fe}_{91}\text{Zr}_7\text{B}_2$ alloy annealed for periods of 60 s–1080 ks, at temperatures of 823–973 K. The highest permeability (at 1 kHz and 0.4 A/m) 31,000 and smallest coercivity 4.2 A/m are obtained for the sample annealed at 923 K for 60 s, where a small grain size (≈ 12 nm) and about 35% of the residual amorphous phase are measured. The coercivity of the nanocrystalline alloy varies as the 3^{rd} power of the grain size, corresponding to the case where the magnetically coupled region has a dimensionality between two and three. This slightly low dimensionality is presumed to be due to the alignment of the magnetization in the sample plane. © 1996 American Institute of Physics. [S0021-8979(96)29308-7]

I. INTRODUCTION

Nanocrystalline soft magnetic alloys consisting of bcc nano crystallites embedded in an amorphous matrix have been produced^{1–5} by primary crystallization of melt-spun amorphous ribbons. Among the nanocrystalline soft magnetic alloys, the $\text{Fe}_{91}\text{Zr}_7\text{B}_2$ alloy is particularly attractive because of its high saturation magnetization (≈ 1.7 T)³.

The magnetic softness of the nanocrystalline Fe–Zr–B alloys depends strongly on annealing conditions such as annealing temperature and heating rate.⁶ However, in most of the previous reports on Fe–M–B ($M=\text{Zr}$, Hf, and Nb) alloys,⁷ the nanocrystalline phase was obtained by isochronal annealing for 3.6 ks and no systematic study of the annealing conditions with different annealing times has been reported. In this study we have examined the structure, volume fraction of the residual amorphous phase, grain size, magnetostriction, and soft magnetic properties of the amorphous $\text{Fe}_{91}\text{Zr}_7\text{B}_2$ alloy annealed for periods ranging from 60 s to 1080 ks, at several temperatures ranging from 823 to 973 K, with the intention of clarifying the dominant factor as well as the optimum annealing condition to obtain magnetic softness.

II. EXPERIMENTAL PROCEDURE

An amorphous $\text{Fe}_{91}\text{Zr}_7\text{B}_2$ alloy was prepared in an argon atmosphere by single-roller melt spinning. Since a homogeneous nanostructure with good magnetic softness has been prepared⁶ at a high heating rate (>1 K/s) in the Fe–M–B ($M=\text{Zr}$, Hf, and Nb) systems, the amorphous samples were vacuum sealed in quartz tubes and annealed by using a salt bath; the heating rate was ≈ 3 K/s. The mean grain size (D) and the volume fraction of the residual amorphous phase (V_{am}) were evaluated from the peak width of the (110) x-ray reflection and ^{57}Fe Mössbauer results, respectively. To avoid the effect of surface crystallization products on D , the annealed samples were polished. The evaluation of V_{am} was made by assuming the same recoil-free fractions for the bcc

and amorphous phases and that the Fe content of the bcc phase is 98 at. %, which has previously been reported⁸ for the nanocrystalline $\text{Fe}_{90}\text{Zr}_7\text{B}_3$ alloy, using atom-probe field ion microscopy. Coercivity (H_c) and saturation magnetostriction (λ_s) were measured using a dc B - H tracer and a capacitance bridge, respectively. The effective permeability (μ_e) was measured at 1 kHz and 0.4 A/m.

III. RESULTS AND DISCUSSION

A. Soft magnetic properties and nanostructure

Figure 1 shows the annealing time (t_a) and temperature (T_a) dependence of H_c for the amorphous $\text{Fe}_{91}\text{Zr}_7\text{B}_2$ alloy. The annealed structures determined by x-ray diffractometry and Mössbauer spectroscopy are also shown in Fig. 1. A small H_c (<5 A/m) is obtained in a relatively high T_a range (923–973 K) in a very short t_a range (>100 s). The optimum t_a for obtaining low H_c shifts toward longer time periods with decreasing T_a . As shown in Fig. 2, a similar dependence of magnetic softness on t_a and T_a is observed from the change in μ_e .

The onset of primary crystallization for the amorphous $\text{Fe}_{91}\text{Zr}_7\text{B}_2$ alloy was measured to be 830 K at a rate of 3.3 K/s by using a differential scanning calorimeter. Furthermore, it was confirmed that the crystallization reaction is

FIG. 1. Annealing time and temperature dependence of coercivity (H_c).

^{a)}School of Physics, The University of New South Wales.

FIG. 2. Annealing time and temperature dependence of permeability (μ_e).

virtually complete by 920 K. Accordingly, the evolution of the nanoscale bcc phase takes place isochronally at $T_a = 923$ and 973 K, and isothermally at $T_a = 823$ K. Therefore, an isochronal heating at a high heating rate is more appropriate for the formation of the nano structure with good soft magnetic properties rather than a low-temperature isothermal annealing.

In Figs. 1 and 2, the zero magnetostrictive line on which the λ_s value becomes virtually zero is also shown. It is clear that the t_a and T_a for obtaining the optimum magnetic properties do not agree with those for the zero magnetostrictive line, revealing that the magnetic softness in the nanocrystalline $\text{Fe}_{91}\text{Zr}_7\text{B}_2$ alloy is governed by factors other than magnetostriction. It is well established⁹ that the apparent magnetic anisotropy ($\langle K \rangle$) of nanocrystalline materials depends on intergranular magnetic interactions as well as the grain size. Furthermore, the H_c of the nanocrystalline alloys increases with temperature toward the Curie temperature (T_c) of the residual amorphous phase, because the intergranular exchange coupling is inhibited by the nonmagnetic intergranular region. Given the low T_c of Fe-rich amorphous alloys, the temperature dependence of H_c (i.e., dH_c/dT) at room temperature may become positive for the sample in which the residual amorphous phase dominates the magnetic softness through the effectiveness of the intergranular coupling.

Figure 3 shows the relation between the mean grain size of the bcc phase (D) and the annealing conditions (t_a and

FIG. 3. Annealing time and temperature dependence of mean grain size (D).

FIG. 4. Annealing time and temperature dependence of volume fraction of the residual amorphous phase (V_{am}).

T_a) for the $\text{Fe}_{91}\text{Zr}_7\text{B}_2$ alloy. Although a small D (< 13 nm) is obtained at $t_a = 60$ s for all the annealing temperatures, D increases up to ≈ 20 nm with t_a even before the nanocrystalline bcc structure begins to decompose into $\alpha\text{-Fe} + \text{Fe}_3\text{Zr}$. The increase in D in Fig. 3 corresponds to the increase in H_c in Fig. 1, indicating that the grain growth of the nanocrystalline bcc phase is responsible for the degradation of the soft magnetic properties in the longer t_a range. However, high H_c values of 10–60 A/m are seen in a short t_a range ($< 10^4$ s) where a small D (< 13 nm) is confirmed, suggesting that the magnetic softness in the short t_a range is dominated by the intergranular magnetic coupling. Figure 4 shows the relation between V_{am} and the annealing conditions (t_a and T_a). The region where a positive temperature dependence of H_c was confirmed at room temperature is also shown in Fig. 4. It is evident that the area for which high V_{am} values above 0.4 are obtained corresponds to that of high H_c values and furthermore a positive dH_c/dT is confirmed in this area. Consequently, we conclude that the magnetic softness is mostly dominated by D and V_{am} and good soft magnetic properties are obtained for samples with $D < 13$ nm and $V_{am} \approx 0.35$.

B. Random anisotropy model or Ripple theory?

Two theoretical models, the random anisotropy model⁹ and magnetic ripple theory,¹⁰ have been applied to nanocrystalline materials having small D less than the ferromagnetic exchange length ($L_{ex} \approx \sqrt{A/K}$). In both models, a magnetically coupled region in which the effects of magnetocrystalline anisotropy (K) are statistically averaged out is assumed and an expansion of the coupled region or a decrease in the grain size promotes the averaging effect leading to small H_c . The random anisotropy model gives

$$H_c \propto K [D / (A/K)^{1/2}]^{2n/(4-n)}, \quad (1)$$

where A is the exchange stiffness and n is the dimensionality of the coupled region. Since only the exchange interaction is considered as the intergranular interaction in this model, the shape of the coupled region is uniform and is independent of the direction of the magnetic moment. To evaluate the exponent $x [= 2n/(4-n)]$ for the present Fe–Zr–B alloy, the data on H_c and D in Figs. 1 and 3 are replotted in Fig. 5. The data points with $H_c > 8$ A/m in the short t_a range and those

FIG. 5. Relation H_c and D for the nanocrystalline $\text{Fe}_{91}\text{Zr}_7\text{B}_2$ alloy. Data replotted from previous reports on $\text{Fe-Si-B-M-Cu}_{2,5,11}$ and $\text{Fe}_{60}\text{Co}_{30}\text{Zr}_{10}$ alloys are also shown for comparison.

for the samples containing the Fe_3Zr compound are excluded to avoid the influences of parameters other than D . The data from the previous reports on the Fe-Si-B-M-Cu ($M=\text{IVa to VIa metal}$)^{5,9,11} and $\text{Fe}_{60}\text{Co}_{30}\text{Zr}_{10}$ alloys are also plotted in the Fig. 5 for comparison. The exponent x derived from least-squares fitting of the data points in a range $D < L_{\text{ex}}$ (≈ 35 nm) is about 3 for both the Fe-Zr-B and Fe-Si-B-M-Cu alloys, implying that the magnetically coupled region is nonuniform in three-dimensional space ($n < 3$). Given the thickness of the ribbon samples (≈ 20 μm), which is large enough to provide the uniform three-dimensional coupling ($n=3$), this result cannot be explained by Eq. (1).

Unlike the random anisotropy model, the dipole-dipole interaction as well as the exchange interaction is considered in the ripple theory, and thus the shape of the coupled region depends on the direction of the magnetic moment. This theory gives a two-dimensional ellipsoid for the coupled region in thin-film materials, in which the magnetization is fully aligned in the plane. Although the ripple theory for bulk materials has not been established, the theory suggests that the shape of the coupled region in the ribbon samples can be nonuniform ($n < 3$) due to the contribution of the dipole-dipole effect originating from the magnetic texture along the sample plane. To clarify the presence of the magnetic texture in the Fe-Zr-B samples, the average angle between the Fe magnetic moments and the incident γ -ray direction (θ) was evaluated from the ^{57}Fe Mössbauer results. As can be seen in Fig. 6, the magnetic moment tends to align in the ribbon

FIG. 6. Average angle between the Fe magnetic moment and incident γ -ray evaluated from ^{57}Fe Mössbauer measurements as a function of H_c .

plane with decreasing H_c , reflecting that the shape anisotropy dominates the direction of the magnetic moment in samples with low $\langle K \rangle$. Accordingly, the dipole-dipole effect of reducing the dimensionality of the coupled region is presumed to be significant in low H_c samples. This is consistent with the results in Fig. 6 in which a high exponent $x \approx 6$, corresponding to $n \approx 3$, is limited to the $\text{Fe}_{60}\text{Co}_{30}\text{Zr}_{10}$ alloy having relatively high H_c values. Thus, the sample shape can be responsible for the D^3 dependence in the present Fe-Zr-B alloy. An extension of the ripple theory to three-dimensional materials is needed for quantitative discussion.

Soft magnetic properties of Fe–Zr–B thin films (abstract)

N. B. Shevchenko, J. A. Christodoulides, X. Meng-Burany, A. S. Murthy, and
G. C. Hadjipanayis

Department of Physics and Astronomy, University of Delaware, Newark, Delaware 19716

The Fe–Zr–B system has been shown to exhibit superior soft magnetic properties in melt-spun ribbons.¹ These ribbons with composition $\text{Fe}_{87}\text{Zr}_7\text{Cu}_3\text{B}_3$ had very low coercivity (0.02 Oe) and high magnetization (190 emu/g) after crystallization at 540 °C from the amorphous state. We have recently extended these studies to thin films with similar composition. These films were prepared by dc magnetron sputtering from a solid alloy target. Transmission electron microscopy and differential scanning calorimetry were used to study the evolution of the microstructure upon annealing. Magnetic measurements were taken with a hysteresigraph. Unlike the as-spun ribbon samples, the as-sputtered films showed 10 nm crystallinities. Selected area diffraction patterns indicated a two phase microstructure, with the bcc phase which gave rise to the soft magnetic properties in the ribbons, coexisting with a second phase leading to degraded soft magnetic properties ($H_c = 20$ Oe and $M_s = 150$ emu/g). Subsequent annealing of the thin film samples enhanced the formation of the second phase and further degraded the soft magnetic properties. Work is currently underway to determine a means of suppressing the formation of the secondary phase while preserving the phase with superior soft properties. © 1996 American Institute of Physics. We have investigated the effect of cooling rate, followed immediately after the isothermal annealing, on the magnetic properties of melt-spun $\text{Fe}_{88}\text{Zr}_7\text{B}_4\text{Cu}_1$ alloy. As the cooling rate is increased, the effective permeability, 2×10^4 , improved by 50% on annealing at around 650 °C. The remanence ratio is also found to concomitantly decrease with the increasing cooling rate. The increase of permeability and decrease of remanence ratio are consistent with the expected suppression of the induced magnetic anisotropy. From an analysis of the transmission electron microscopy micrographs, and the x-ray diffraction spectral intensities, we find that the volume fraction of the amorphous matrix to that of the nanocrystallized magnetic entities to be about 20%, at which the permeability has the maximum value for this system. Scanning electron microscopy and antiferromagnetic investigations show a much smoother surface morphology with a finer grain distribution in the rapidly quenched sample. © 1996 American Institute of Physics. [S0021-8979(96)29408-3]

During recent years there has been of considerable interest in Fe-based rapid quenched materials which, upon annealing, nanocrystallize into a state with ultrafine bcc-Fe grains. Numerous studies about soft magnetic nanocrystalline materials have been published,^{1,2} including the dependence of the functional properties on annealing conditions. The reason for the good soft magnetic properties of these nanocrystalline materials is understood to be a consequence of the reduction in the effective magnetocrystalline anisotropy on forming ultrafine grains.³ In amorphous alloys it is well known that induced magnetic anisotropy can be effectively suppressed by controlling the quench rate or by annealing the same in a rotating magnetic field.⁴ From the point of view applications, it is thus useful to know how the cooling rate after annealing influences the soft magnetic properties of nanocrystalline alloys. In this article, we investigate and discuss the effect of cooling rate after annealing $\text{Fe}_{88}\text{Zr}_7\text{B}_4\text{Cu}_1$ nanocrystalline alloys which are known to exhibit soft magnetic properties with high saturation magnetization and permeability.⁵ Scanning electron microscopy (SEM) and atomic force microscopy (AFM) surface morphology characterizations shows a finer grain distribution and much smoother surface in the rapidly quenched sample, resulting in low coercivity and good soft magnetic properties.

Amorphous $\text{Fe}_{88}\text{Zr}_7\text{B}_4\text{Cu}_1$ alloy ribbons were prepared by the well-known single roller melt spinning technique. The ribbons obtained were 20 μm thick and about 2 mm wide. They were wound into toroidal cores and annealed for 1 h above their crystallization temperatures T_{x1} in N_2 gas atmosphere. The structure of the samples was examined by x-ray diffractometer using $\text{Cu } \alpha$ radiation and transmission electron microscopy (TEM). The cooling rate after annealing was varied by carrying out two different methods: (a) by slow cooling to a vacuum-sealed specimen to ambient condi-

tions, and (b) by water quenching the sample in an Ar gas atmosphere after vacuum annealing. The effective permeability was measured at 1 kHz and 0.8 A/m with an impedance analyzer. The magnetic induction at 800 A/m and coercive force were measured with a dc hysteresis loop tracer. The saturation magnetization measurements were carried out by means of a superconducting quantum interference device (SQUID) magnetometer in a field of 1 T in the temperature range 5–300 K. The features of surface quality of the ribbon were investigated with SEM and AFM.

The amorphous $\text{Fe}_{88}\text{Zr}_7\text{B}_4\text{Cu}_1$ alloy was annealed at various temperatures above the first crystallization temperature, 471 °C, in order to form nanocrystallites. Figure 1 shows the effective permeability (μ_e) and magnetic coercivity (H_c) of $\text{Fe}_{88}\text{Zr}_7\text{B}_4\text{Cu}_1$ alloy as a function of the annealing temperature. The effective permeability of the alloys increased with annealing temperatures. Especially, as the cooling rate

FIG. 1. The effective permeability (μ_e) at 1 kHz and magnetic coercivity (H_c) as a function of annealing temperature for $\text{Fe}_{88}\text{Zr}_7\text{B}_4\text{Cu}_1$ alloy on fast and slow cooling, respectively.

FIG. 2. The remanence ratio (B_r/B_{10}) as a function of annealing temperature for $\text{Fe}_{88}\text{Zr}_7\text{B}_4\text{Cu}_1$ alloy on fast and slow cooling, respectively.

FIG. 3. The spin-wave stiffness (D) as a function of annealing temperature for $\text{Fe}_{88}\text{Zr}_7\text{B}_4\text{Cu}_1$ alloy fast and slow cooling, respectively.

increased, the effective permeability, 2.1×10^4 , improved by 50% on annealing at 650 °C. On the other hand, although not shown in the figure, μ_e values decrease drastically on annealing the samples above 650 °C. The coercive field is found to be consistently smaller for samples processed with a higher cooling rate at all annealing temperatures and reaches values as low as 3 A/m (~ 38 mOe). Notice from high that H_c decreases monotonically with increasing annealing temperatures. It is useful to point out that on annealing above 650 °C, H_c is found to increase drastically. This is consistent with the TEM morphology studies, which show larger grain growth and intergranular structures on annealing above 650 °C (see Fig. 4 which will be discussed later).

Figure 2 shows the remanence ratio (B_r/B_{10}) as a function of annealing temperature. The remanence ratio is a measure of the distribution of domain orientation and is strongly correlated with the induced magnetic anisotropy. In ribbon-type amorphous and nanocrystalline materials, most of the spontaneous magnetization is aligned in the direction of the ribbon axis because the self-induced magnetic anisotropy is considered to form along this direction due to stress effects during the casting of the ribbons. Notice that the remanence ratios for the samples cooled at the higher rate are all smaller than those for the more slowly cooled samples, suggesting that the rapid cooling suppresses the induced anisotropy. The above studies thus show consistently that higher cooling rate has an advantage in obtaining higher permeability and good soft magnetic properties. Furthermore, because of rapid cooling from the higher annealing temperature a fine scale random distribution of the nanostructured particles is obtained. This decreases further the effective local anisotropy and hence results in lower H_c and higher μ_e .

In a nanocrystallized sample the temperature dependence of the magnetization would reflect the effect of annealing on the stiffness constant of the amorphous matrix as well as that of the nanocrystallized magnetic entities. This is specially so because it is well known that the spin-wave stiffness constant in an amorphous material is half of that for the crystalline analog. At low temperatures, the magnetization $M(T)$ is well described in terms of the spin-wave approximation

$$[M(T) - M(0)]/M(0) = BT^{3/2} + CT^{5/2}. \quad (1)$$

The Bloch coefficient B , which is the thermal average of the total contribution arising from spin waves of all wavelengths, is related to the spin-wave stiffness, D , through the expression⁶

$$D = \xi(3/2)^{2/3} [g \mu_B / M(0) B] (k_B / 4\pi), \quad (2)$$

where $\xi(3/2)$ is the Riemann zeta function and g is the spectroscopic splitting g factor. Figure 3 shows the spin-wave stiffness, D , as a function of annealing temperature for the two different cooling rates. The values of D were determined from a fit to the SQUID magnetic data in the temperature range within 5–200 K. As seen in Fig. 3, it is found that the

FIG. 4. The bright- and dark-field electron micrograph and selected-area electron diffraction for $\text{Fe}_{88}\text{Zr}_7\text{B}_4\text{Cu}_1$ alloy as a function of annealing temperature. The annealing conditions are (a) as-quenched, (b) 600 °C, (c) 650 °C, and (d) 700 °C.

FIG. 5. The volume fraction of residual amorphous phase and effective permeability for the sample cooled at the higher rate as a function of annealing temperatures for $\text{Fe}_{88}\text{Zr}_7\text{B}_4\text{Cu}_1$ alloy.

values for D change from $172.3 \text{ meV } \text{\AA}^2$ to as much as $226.8 \text{ meV } \text{\AA}^2$ on fast cooling from 650°C . Furthermore, the value of D is consistently higher for the fast quenched state and for the 650°C annealed sample the difference is as much as about 4%. From the observed changes in the value of D on annealing we estimate volume fraction of the nano crystal assuming the value of D for pure Fe from literature.⁷ In Figure 4 is shown the bright and dark field electron micrograph and selected-area electron diffraction pattern of the samples as a function of annealing temperature. Clearly, while nanocrystallized particle size, 7–12 nm, does not change very much on annealing the sample up to 650°C , drastic changes in the morphology along with intergranular effects are observed on annealing at higher temperature.

In order to evaluate the fraction of the residual amorphous phase, we used TEM analysis as well as the XRD data. We used line fitting pattern of crystalline and amorphous peaks of the samples obtained by x-ray diffraction pattern and the ratio between crystallites and amorphous matrix in TEM micrographics. We estimate the amorphous phase correlates well with a simple evaluation using the magnetic data taking into consideration independent contributions to the magnetization from the amorphous matrix and the nanocrystals. Figure 5 represents the volume fraction of the residual amorphous phase and the effective permeability for the sample cooled at the higher rate. Our previous studies⁸ on these samples show that the saturation magnetostriction of $\text{Fe}_{88}\text{Zr}_7\text{B}_4\text{Cu}_1$ alloy also has a minimum value of nearly zero when annealed in the temperature regime around $620\text{--}650^\circ\text{C}$. Furthermore, over the same annealing temperature interval the volume fraction of the residual amorphous phase is found to remain nearly the same. However, the permeability for the sample annealed at 650°C is higher than that observed for the 620°C annealed sample. Hence, this result shows that low saturation magnetostriction is not the only important factor for obtaining soft magnetic properties. In this case we argue that the permeability is limited by magnetocrystalline anisotropy and that it can be suppressed by a high cooling rate after annealing.

FIG. 6. The AFM surface morphology of the samples' different cooling rates after nano crystallizing $\text{Fe}_{88}\text{Zr}_7\text{B}_4\text{Cu}_1$ alloy at 650°C with (a) high cooling rate and (b) low cooling rate.

The surface microstructures arising from the different cooling rates after annealing have been investigated using SEM and AFM. Figure 6 shows the AFM images for samples with two cooling rates. It can be noticed that the surface morphology is significantly smoother after cooling at the higher rate. Furthermore, from a chemical analysis energy-dispersive x ray (EDX), we find that the surface of the slowly cooled sample has an increasing tendency to oxidize. Thus the slow cooled sample with a rougher more inhomogeneous grain distribution appears to provide additional domain pinning centers and result in higher coercivity values. Undoubtedly more detailed comparison to establish the relationship of the microstructure to the obtained coercivity values would be desirable.

In summary, we have studied the magnetic properties of nanocrystalline $\text{Fe}_{88}\text{Zr}_7\text{B}_4\text{Cu}_1$ alloy cooled at different rates after annealing. The increase of permeability, decrease of remanence ratio, as well as decrease in the magnetic coercivity H_c to values as low as 3 A/m are consistent with the expected suppression of the induced magnetic anisotropy. From TEM microstructural analysis and XRD peak we estimate the volume fraction of the amorphous matrix to that of the nanocrystallized magnetic entities. Finally, SEM(EDX) and AFM surface morphology studies are shown to evidence a random distribution of fine nanocrystalline entities and a much finer surface profile for the sample rapidly cooled directly from the annealing temperatures.

Improvement of soft magnetism of $\text{Fe}_{90}\text{Co}_{10}$ sputtered films by addition of N and Ta

Shigeki Nakagawa, Satoshi Tanaka, Katsumi Suemitsu, and Masahiko Naoe
Department of Physical Electronics, Tokyo Institute of Technology, Meguro, Tokyo 152, Japan

The addition of Ta and N into sputtered $\text{Fe}_{90}\text{Co}_{10}$ alloy films was performed to attain soft magnetism with large saturation magnetization $4\pi M_s$. Addition of Ta below 8 at. % to $\text{Fe}_{90}\text{Co}_{10}$ films improved their crystallinity and the lattice constant of Fe crystallites was expanded. These films revealed relatively large $4\pi M_s$ of about 21 kG. The deposition of Fe-Co and Fe-Co-Ta films at N_2 partial pressure P_{N_2} below 0.1 m Torr was so effective as to cause fine granulation in the film. $\text{Fe}_{84.6}\text{Co}_{8.4}\text{Ta}_{7.1}\text{N}$ films deposited at P_{N_2} of about 0.2 mTorr and postannealed at 150 °C revealed $4\pi M_s$ and relative permeability μ_r of about 16 kG and 1500, respectively. © 1996 American Institute of Physics. I. INTRODUCTION

Magnetic thin films with large saturation magnetization $4\pi M_s$ deposited on thin polymer sheet substrate are regarded as promising candidates for many applications, such as core materials in micromagnetic devices and the backlayers in double layered media for perpendicular magnetic recording.¹ The important requirements for these thin films are that they exhibit large $4\pi M_s$ and high relative permeability μ_r . Furthermore, they should be deposited at low substrate temperature T_s because of low heat resistance of the substrates. Although thin films of Fe-Ni and Fe-Si-Al alloys have been used as the soft magnetic layers, $4\pi M_s$ of them were relatively small below 12 kG. $\text{Fe}_{90}\text{Co}_{10}$ alloy has an extremely large $4\pi M_s$ of about 24 kG. However, $\text{Fe}_{90}\text{Co}_{10}$ alloy has a bcc crystalline phase and large saturation magnetostriction constant λ_s of about 1.5×10^{-5} . Then, it is required to reduce λ_s and grain size of the films in order to improve the soft magnetism of $\text{Fe}_{90}\text{Co}_{10}$ thin films. Iron nitride Fe-N thin films were widely investigated as soft magnetic thin films for many applications mentioned above.² In addition, Fe-Ta-N thin films were also found as the soft magnetic core layers in MIG-type VTR heads with high performance of recording characteristics.^{3,4} In this study, N and Ta were added into $\text{Fe}_{90}\text{Co}_{10}$ thin films during sputtering in order to improve the soft magnetism through the effects of reduction of grain size.

II. EXPERIMENTAL PROCEDURE

Specimen films were deposited by the facing targets sputtering apparatus. $\text{Fe}_{90}\text{Co}_{10}$ alloy plates were used as targets. Fe-Co-N and Fe-Co-Ta-N films were deposited by reactive sputtering method using mixture gas of N_2 and Kr. Total pressure of the mixture gas was set at 1 m Torr, and the N_2 partial pressure P_{N_2} was adjusted to control the N contents in deposited films. Ta was added into $\text{Fe}_{90}\text{Co}_{10}$ films by using the composite targets in which Ta sheet plates were placed on $\text{Fe}_{90}\text{Co}_{10}$ targets. The films were deposited on polyethylene naphthalate (PEN) tape substrates at room temperature. Si wafers were also used as the substrates for investigating postannealing effect. Thickness of the films was about 200 nm. Annealing treatments were performed at a temperature of 150 °C in an evacuated chamber for 1 h. Film

composition was analyzed by inductively coupled plasma (ICP) analysis. Crystallographic and magnetic characteristic were analyzed by x-ray diffractometry (XRD) and the vibrating-sample magnetometer (VSM), respectively.

III. RESULTS AND DISCUSSION

From x-ray diffraction (XRD) patterns, $\text{Fe}_{90}\text{Co}_{10}$ films revealed a bcc-Fe crystalline phase with (110) orientation, but the crystalline phase was degraded monotonically with increase of N_2 partial pressure P_{N_2} . The addition of N to $\text{Fe}_{90}\text{Co}_{10}$ films seemed effective to enhance the fine granulation of crystallites in the films and to expand the lattice parameter. The formation of $\gamma\text{-Fe}_4\text{N}$ phase was not observed in these films.

Figure 1 shows the variation of XRD patterns of $(\text{Fe}_{90}\text{Co}_{10})_{100-x}\text{Ta}_x$ films for various Ta content x . Addition of Ta up to 10% improved the crystallite growth and caused the significant shift of peak in XRD patterns. It was not clarified whether the peak shift toward the lower side of the diffraction angle means the expansion of lattice of $\alpha\text{-Fe}$ crystallites or the appearance of other phases, such as Fe_7Ta_3 and Fe_2Ta . Excessive Ta content above 9 at. % caused the degra-

FIG. 1. X-ray diffraction patterns of $(\text{Fe}_{90}\text{Co}_{10})_{100-x}\text{Ta}_x$ films for various Ta content x .

FIG. 2. Changes of $4\pi M_s$ and H_c of $(\text{Fe}_{90}\text{Co}_{10})_{100-x}\text{Ta}_x$ films as a function of Ta content x .

dation of crystallinity. Figure 2 shows the changes of $4\pi M_s$, and coercivity H_c of $(\text{Fe}_{90}\text{Co}_{10})_{100-x}\text{Ta}_x$ films as a function of Ta content x . $\text{Fe}_{90}\text{Co}_{10}$ films exhibited a large $4\pi M_s$ of about 24 kG. Such a large $4\pi M_s$ decreased gradually to about 22 kG with increase of Ta content x up to about 8 at. %. Although excessive Ta content above 8 at. % caused the significant degradation of $4\pi M_s$, $(\text{Fe}_{90}\text{Co}_{10})_{91}\text{Ta}_9$ films exhibited relatively large $4\pi M_s$ of about 17 kG. These films with such a large $4\pi M_s$ are suitable for practical applications as soft magnetic flux path. However, these films exhibited relatively high coercivity H_c of about several tenths Oe. Such high coercivity seemed to be originated from the crystalline anisotropy because crystallite growth was observed in the films, as shown in Fig. 1. Since it seemed necessary for attaining good soft magnetism to cause fine granulation of crystallites in $\text{Fe}_{90}\text{Co}_{10}$ films, the addition of N to $(\text{Fe}_{90}\text{Co}_{10})_{100-x}\text{Ta}_x$ was investigated.

FIG. 3. P_{N_2} dependence of diffraction intensity I_p and grain size $\langle D \rangle$ of $\text{Fe}_{90}\text{Co}_{10}:\text{N}$ and $\text{Fe}_{84.6}\text{Co}_{8.4}\text{Ta}_7:\text{N}$ films.

FIG. 4. $4\pi M_s$ of $\text{Fe}_{90}\text{Co}_{10}:\text{N}$ and $\text{Fe}_{84.6}\text{Co}_{8.4}\text{Ta}_7:\text{N}$ films as a function of P_{N_2} .

From XRD patterns, it was observed that the addition of N into $\text{Fe}_{84.6}\text{Co}_{8.4}\text{Ta}_7$ films caused a drastic decrease in height and broadening of the peak, which means fine granulation. Furthermore, peak shift was also observed for films deposited at higher P_{N_2} . Figure 3 shows the P_{N_2} dependence of diffraction intensity I_p and crystallite size $\langle D \rangle$ of $\text{Fe}_{90}\text{Co}_{10}:\text{N}$ and $\text{Fe}_{84.6}\text{Co}_{8.4}\text{Ta}_7:\text{N}$ films evaluated on the XRD patterns, as shown in Fig. 2. The addition of a small amount of N caused a drastic decrease of I_p and $\langle D \rangle$, especially for Fe-Co-Ta films. However, crystalline phase was observed in Fe-Co:N films even at P_{N_2} as high as about 0.1 m Torr. This crystalline phase seems to correspond to $\alpha\text{-Fe}$ or $\epsilon\text{-Fe}_{2-3}\text{N}$ phases. On the contrary, such crystalline phase was not observed in $\text{Fe}_{84.6}\text{Co}_{8.4}\text{Ta}_7:\text{N}$ films deposited at P_{N_2} around 0.1 m Torr, so that they looked amorphouslike.

Figure 4 shows the changes of $4\pi M_s$ of $\text{Fe}_{90}\text{Co}_{10}:\text{N}$ and $\text{Fe}_{84.6}\text{Co}_{8.4}\text{Ta}_7:\text{N}$ films as a function of P_{N_2} . Deposition at

FIG. 5. Change of μ_r of $\text{Fe}_{90}\text{Co}_{10}:\text{N}$ and $\text{Fe}_{84.6}\text{Co}_{8.4}\text{Ta}_7:\text{N}$ films after post-annealing at 150°C as a function of P_{N_2} .

P_{N_2} as low as 0.02 m Torr caused the decrease of $4\pi M_s$ from 24 to 20 kG and from 22 to 17 kG for $Fe_{90}Co_{10}:N$ and $Fe_{84.6}Co_{8.4}Ta_{7}:N$ films, respectively. The decrease of $4\pi M_s$ from 18 to 15 kG was also observed at P_{N_2} higher than 0.1 m Torr for $Fe_{90}Co_{10}:N$ films. The decrease seemed to originate from the existence of $Fe_{2-3}N$ crystallites in the films. On the contrary, $4\pi M_s$ of $Fe_{84.6}Co_{8.4}Ta_{7}:N$ films was around 17 kG at P_{N_2} up to 0.2 m Torr. All of as-deposited films, however, exhibited their permeability μ_r of about 200 in spite of the addition of nitrogen.

The annealing process at the relatively low temperature of 150 °C significantly improved the soft magnetism. Figure 5 shows the change of μ_r of $Fe_{90}Co_{10}:N$ and $Fe_{84.6}Co_{8.4}Ta_{7}:N$ films postannealed at 150 °C as a function of P_{N_2} . Although a slight increase of μ_r for $Fe_{90}Co_{10}:N$ films was observed at P_{N_2} around 0.06 m Torr, μ_r of $Fe_{90}Co_{10}:N$ films were relatively low. On the contrary, $Fe_{84.6}Co_{8.4}Ta_{7}:N$ films exhibited relatively high μ_r of about 500 at P_{N_2} around 0.1 m Torr. Furthermore, $Fe_{84.6}Co_{8.4}Ta_{7}:N$ films deposited at P_{N_2} of about 0.3 m Torr exhibited high μ_r of about 1600. These films with such a high μ_r may be applicable for core materials in micromagnetic devices and the backlayers in recording media. These results seemed to originate from both the fine granulation of Fe-Co crystallites by nitridation and the drastic decrease of saturation magnetostriction constant λ_s of $Fe_{84.6}Co_{8.4}Ta_{7}:N$ films. Although λ_s of $Fe_{90}Co_{10}$ films is about 1.5×10^{-5} , it was successfully decreased to the order of 10^{-6} by the addition of Ta and N to Fe-Co films.

IV. CONCLUSION

The addition of Ta and N to $Fe_{90}Co_{10}$ alloy films sputter-deposited on polymer tape substrate was investigated to attain soft magnetism with large $4\pi M_s$ and high μ_r . The results obtained in this study were summarized as follows:

- (1) Addition of Ta atoms to $Fe_{90}Co_{10}$ enhanced the crystallite growth and caused lattice expansion of Fe crystallites while Ta content is below 8 at. %. These films exhibited relatively large $4\pi M_s$ of about 22 kG. Excessive Ta content above 8 at. % caused degradation of crystallinity and decrease of $4\pi M_s$.
- (2) Introduction of a small amount of N_2 into the reactive sputtering chamber was so effective as to cause fine granulation of crystallites in Fe-Co films, and especially in Fe-Co-Ta ones.
- (3) $Fe_{84.6}Co_{8.4}Ta_{7}:N$ films deposited at P_{N_2} of about 0.2 m Torr and postannealed at 150 °C exhibited $4\pi M_s$ and μ_r about 16 kG and 1500, respectively.

Consequently, these Fe-Co-Ta:N films may be applicable to the practical applications, especially to the backlayers in double layered magnetic tapes.

The effect of nitrogen interstitial in α -Fe crystalline on the magnetic soft properties of $\text{Fe}_{87.5}\text{Ta}_{12.5}\text{N}_x$ films has been investigated. The magnetic soft properties can be improved by carefully controlling the nitrogen flow ratio during sputtering and the postannealing to result in a film with fine grain size and low magnetostriction. Using x-ray diffraction technique, the nitrogen content in the α -Fe crystalline of FeTaN film can be estimated from the effect of lattice expansion of α -Fe crystalline due to nitrogen interstitial. It is found that the film with about 7.5 at. % N_2 in α -Fe crystalline exhibits the best magnetic soft properties of $B_r=1.6$ T, $H_c=0.2$ Oe and $\mu_i(1 \text{ MHz})=3400$, respectively. X-ray diffraction analysis is found to provide a proper and an easy way to identify the suitable condition for growing excellent magnetic soft FeTaN thin films. © 1996 American Institute of Physics. I. INTRODUCTION

Magnetic soft FeTaN thin films have been reported to be good candidates, superior to sendust (FeAlSi), to act as a metallic layer in metal-in-gap head for increasing the gap field while writing a high coercivity recording media. The virtues of FeTaN films include high saturation magnetization, very low coercivity, and high permeability in the high-frequency region.^{1,2} Their excellent magnetic soft properties are primarily contributed by the formation of TaN phase during annealing treatment to prevent α -Fe grains from growing over nanometer scale, so-called nanocrystalline structure.³ The nanometer scale α -Fe grains can effectively reduce their magnetic anisotropy energy through the micromagnetic interaction among them.⁴ The key factor is that one should introduce a suitable content of nitrogen atom to the film during sputtering to meet the above purpose^{2,5} and also a certain amount of magnetostriction intrinsic to the microcrystalline magnetic soft film is necessary to ensure high permeability.⁴ The suitable nitrogen content needed inside the film is normally dependent upon the content of Ta in the film, where the nitrogen content of the films were usually identified with electron spectroscopy for chemical analysis (ESCA) or Auger spectrometer. To the best of our knowledge, it seems that no article has ever mentioned the effect of nitrogen in α -Fe crystalline on the magnetic properties of FeTaN films. In this study, we have paid very special attention to the effects of nitrogen flow and annealing temperature on the variation of α -Fe (110) lattice spacing and on the nitrogen content in α -Fe, evaluating the same from x-ray diffraction analysis. Finally, their relationship with the magnetic properties of the $(\text{Fe}_{87.5}\text{Ta}_{12.5})\text{N}_x$ films will be discussed.

II. EXPERIMENT

The target material with the normal composition $\text{Fe}_{87.5}\text{Ta}_{12.5}$ was melted from 99.9 wt % Ta and 99.999 wt % Fe metal with vacuum induction furnace, and then the melt was cast in a copper mold 2 in. in diameter. The

$(\text{Fe}_{87.5}\text{Ta}_{12.5})\text{N}_x$ films were sputtered on recrystallized glass, 1 cm \times 1 cm \times 0.05 cm in size, using a dc sputtering apparatus. The surfaces of the target and substrate are parallel while the distance was kept at 6 cm. In order to obtain FeTaN films with various nitrogen content, argon gas, 10 and 15 sccm, in combination with nitrogen gas, flow ratio ($R(\text{N}_2) = F(\text{N}_2)/[F(\text{Ar}) + F(\text{N}_2)]$) in the range from 8% to 15%, was regulated and flown into the vacuum chamber for reactive sputtering. After sputtering, a thin SiO_2 film, about 100 Å thick, was sputtered on the FeTaN film in order to prevent oxidation during the subsequent annealing process. Annealing treatment was performed at 425–500 °C for 30 min. An x-ray diffractometer with Cu $K\alpha$ radiation was adopted to analyze the crystallinity of the as-sputtered and postannealed films. Lattice constant of the α -Fe crystal of the postannealed films was calculated from their α -Fe(110) lattice spacing. The magnetic properties of the films were measured with a vibrating-sample magnetometer (VSM) and with a LCR meter. The N_2 content in the α -Fe crystal of the films was estimated from the relationship of α -Fe(110) lattice spacing versus the amount of nitrogen interstitial reported by Kusumi *et al.*⁷

III. RESULTS AND DISCUSSION

Figure 1 exhibits the diffraction patterns of the as-deposited and postannealed, from 425 to 500 °C, $(\text{Fe}_{87.5}\text{Ta}_{12.5})\text{N}_x$ films sputtered under 15 sccm Ar and 8% N_2 atmosphere. For the as-deposited film, no diffraction peak arising from the film has been found, confirming that the film is in the amorphous state. After annealing at 425 °C or higher temperature, a broad but low intensity α -Fe (110) peak appears reflecting that the grain size of α -Fe is quite small. The diffraction peak of TaN phase is also not found due to its small size. One thing to be noted is that the 2θ position of those α -Fe (110) peaks is lower than 44.2°, which is lower than 44.7° of a pure α -Fe (110) peak, implying that the lattice spacing of α -Fe crystal is expanded. In other words, the co-sputtered N atoms were not all combined with

FIG. 1. X-ray diffraction patterns of the films sputtered under 15 sccm argon gas and 8% nitrogen gas flow ratio (500 °C anneal).

Ta to form TaN to impede α -Fe grains from growing; instead many of them were interstitial in α -Fe crystal after crystallization. The value $\Delta(2\theta)$, defined as $44.7^\circ - (2\theta)_{\alpha\text{-Fe}(110)}$, corresponds to the nitrogen content inside the α -Fe crystal. The larger the $\Delta(2\theta)$ the higher the nitrogen interstitial in the α -Fe crystal is. Figure 2 shows the variation of 2θ position of α -Fe (110) peak of the films sputtered under different atmosphere and followed by 450 and 500 °C annealing. It can be seen that the value of 2θ is obviously decreased with increasing quantity of Ar flow and the N_2 flow ratio. However, increasing the annealing temperature results in a slight increase of 2θ in high N_2 flow ratio ($\geq 12\%$) region, but a large increase in low N_2 region ($< 12\%$). In other words, too large N_2 flow during sputtering is always accompanied by an over-quantity nitrogen atom interstitial in the α -Fe phase after crystallization, and this might result in the increase of its magnetostriction⁶ and deteriorate the magnetic soft properties rapidly. Accordingly, except for supplying enough nitrogen to form TaN phase to impede α -Fe grains from over

FIG. 2. The variation of 2θ position of α -Fe(110) peak with nitrogen flow ratio in various films.

FIG. 3. The variation of B_r , H_c , μ_i and lattice constant, a , with nitrogen flow ratio for the films ($0.6 \mu\text{m}$ thick) sputtered under 15 sccm argon gas.

growing, controlling the suitable nitrogen flow to prevent excessive nitrogen interstitial in α -Fe crystalline should also be considered.

Figures 3 and 4 demonstrate the effect of nitrogen flow ratio on the α -Fe lattice constant, a , and the magnetic properties, B_s , H_c , and μ_i (1 MHz), of the films sputtered under 15 and 10 sccm argon gas flow, respectively. For the former, it is clear that lattice constant a and coercivity H_c increase and in reverse B_s and μ_i decrease with increasing N_2 flow ratio. The magnetic soft properties, especially H_c and μ_i , are still not magnetic soft in this case. For the latter, the trend of a , H_c , B_s , and μ_i changing with N_2 flow ratio is almost the same as that in the previous case, however, after reducing the argon gas flow from 15 to 10 sccm, an excellent magnetic

FIG. 4. The variation of B_r , H_c , μ_i , and lattice constant, a , with nitrogen flow ratio for the films ($0.6 \mu\text{m}$ thick) sputtered under 10 sccm argon gas.

FIG. 5. The frequency response of μ_i of the film with the best magnetic soft properties in this study (10 sccm Ar, 8% N_2 flow ratio and 500 °C anneal).

soft property, $B_s = 1.6$ T, $H_c = 0.2$ Oe, and $\mu_i(1 \text{ MHz}) = 3400$, is achieved in the film sputtered at 8% N_2 flow ratio. In this film, the lattice constant, a , has already reduced to 2.893 Å, while it is still larger than 2.876 Å, the value of a nitrogen free α -Fe crystal. Figure 5 shows its frequency response of μ_i indicating that the permeability of the film is also very stable in the high-frequency region.

As mentioned before, too many nitrogen interstitials in α -Fe grains may deteriorate the magnetic soft properties of FeTaN films, whereas the nitrogen content of the films can only be detected more precisely with ESCA and Auger spectroscopy. Due to the large spot size of the electron beam in the above two spectroscopy and also too small grain size of the α -Fe and TaN phases, a true nitrogen content in α -Fe crystal can hardly be precisely detected individually. However, if one knows the variation of α -Fe (110) lattice spacing with the nitrogen concentration in it, the interstitial nitrogen content in α -Fe crystal of the FeTaN films can be evaluated. Fortunately, Kusumi *et al.* had established a relationship concerning the dependence of lattice constant of α -Fe (110) crystal with the nitrogen concentration in $Fe_{1-x}N_x$ films in their latest study.⁷ Although the data have much scatter, a linear relationship between the lattice constant of α -Fe and the nitrogen concentration in the film was found. After intra fitting our experimental results of the films sputtered with various atmosphere and followed by 500 °C annealing in their figure, as shown in Fig. 6, the nitrogen content in the α -Fe crystalline of the studied FeTaN films can be estimated. It was found that about 7.5 at. % nitrogen, after the forma-

FIG. 6. Intra fitting of the α -Fe lattice constant of some studied films on the figure of lattice constant vs nitrogen content of the $Fe_{1-x}N_x$ films plotted by Kusumi *et al.*⁷

tion of TaN phase, is estimated existing in α -Fe crystal of the $(Fe_{87.5}Ta_{12.5})N_x$ film with the best magnetic soft properties (film sputtered under 10 sccm Ar and 8% nitrogen flow ratio then followed by 500 °C annealing). Excess nitrogen content in α -Fe crystalline would lead to the increment of magnetostriction to deteriorate the magnetic soft properties of the films rapidly. From the above results, in addition to the control of the grain size of α -Fe crystal, controlling the content of nitrogen interstitial in α -Fe crystal by x-ray diffraction analysis might be a proper and an easy way to justify the suitable condition for growing excellent magnetic soft Fe-TaN thin films.

We present the study of the giant magnetoresistance effect in ferromagnetically ordered thin film and bulk based on the Hund's rule coupling between the mobile d electron and the core spin of Mn ions. It has been shown that the resistivity is proportional to the spin-spin correlation functions, a maximum resistivity appears near the critical point in absence of magnetic field and an applied field drives the resistivity peak to higher temperature and reduces the peak value, which is in agreement with the experiments. The giant magnetoresistance effect in thin film is attributed to the spin-correlation-dependent scattering and the low-dimensional character. © 1996 American Institute of Physics. I. INTRODUCTION

Recently negative magnetoresistance (MR) has been found in perovskitelike ferromagnetic semiconductive thin films, such as in the films of $\text{La}_{1-x}\text{Ba}_x\text{MnO}_3$,¹ $\text{La}_{1-x}\text{Sr}_x\text{MnO}_3$,² $\text{La}_{1-x}\text{Ca}_x\text{MnO}_3$ (Ref. 3) and $\text{Nd}_{1-x}\text{Sr}_x\text{MnO}_3$.⁴ Their MR ratios $[(R_B - R_0)/R_B]$ reported are much larger than those found in magnetic multilayers. Especially, in epitaxial $\text{La}_{1-x}\text{Ca}_x\text{MnO}_3$ and $\text{Nd}_{1-x}\text{Sr}_x\text{MnO}_3$ thin films, MR ratios are found to be $\sim 10^3$ – 10^4 under magnetic field $B=6$ T. More recently a giant MR ratio is also found to be in excess of 10^2 for polycrystalline La-Y-Ca-Mn-O compounds.⁵ These remarkable findings can provide promising industrial applications in devices. It also brings us an interesting problem, namely, the mechanism of exhibiting such a giant MR in these ferromagnetic transition-metal-oxide compounds.

Some mechanisms¹⁻⁸ have been suggested to explain the experimental findings. These studies provide in depth investigations for the problem of interest. However, it seems to us that these proposed mechanisms do not provide a satisfactory answer. The double exchange and magnetic polaron transfer mechanism suggested by some authors¹⁻⁵ can explain qualitatively the semiconductive behavior in conduction and the negative temperature coefficient of the resistivity above T_c in the $\text{La}_{1-x}\text{R}_x\text{MnO}_3$ compounds. However, as pointed out by Millis *et al.*,⁶ there exist crucial quantitative discrepancies between the experiments and the theory for the resistivity behavior in an external field, besides, it seems to be hard to form magnetic polaron in the heavy doped La-R-Mn-O and Nd-R-Mn-O systems. In the spin-disorder scattering mechanism,⁷ the huge MR ratio is attributed to the alignment of the canting of manganese spins in the strong external field. However, as indicated by the experiments,^{3,4} the magnetization saturates in a not large magnetic field, and increasing

magnetic field further does not change the spin configurations any more, so the spin-disorder scattering mechanism is not responsible for the change of resistivity by several orders in magnitude under the high magnetic field.

In this article, we present another possible mechanism of the giant MR in these ferromagnetic semiconductive materials. The model and formalism is described in Sec. II, the theoretical curves is calculated in Sec. III, the discussion and conclusion is given in Sec. IV.

II. MODEL HAMILTONIAN

In the La-R-Mn-O or Nd-R-Mn-O compounds, the three $3d$ electrons of Mn^{+4} ions at the low level, t_g , can be considered as the localized spin S_i of the ferromagnetic background, the outer-shell $3d$ electron of Mn^{+3} ions at the high level, e_g , can hop and transfer between different Mn sites as an itinerant one, and is responsible for the electric conduction. In such a model, the outer d electron interacts with the core localized spin through the Hund's rule coupling, the Hamiltonian can be expressed as

$$H = H_0 + V, \quad (1)$$

$$H_0 = \sum_{k\sigma} (\epsilon_k - \sigma\mu_B B) c_{k\sigma}^\dagger c_{k\sigma} - \sum_{\langle ij \rangle} A \mathbf{S}_i \cdot \mathbf{S}_j - \sum_i g\mu_B B S_i^z, \quad (2)$$

$$V = -\frac{J}{N} \sum_{ikq} \sum_{\mu\nu} e^{iq \cdot \mathbf{R}_i} \mathbf{S}_i \cdot c_{k+q\mu}^\dagger \sigma_{\mu\nu} c_{k\nu}. \quad (3)$$

Here ϵ_k is the energy spectrum of conduction electrons with respect to the chemical potential μ , A the effective ferromagnetic exchange constant between manganese ions, and only

FIG. 1. Magnetization and resistivity of La-Sr-Mn-O bulks with respect to temperatures under different magnetic fields, here $J=300$ K, $T_c=140$ K. (1) Magnetization in $B=2$ T, (2) resistivity in $B=6$ T, and (3) resistivity in $B=8$ T.

the nearest-neighbor interaction is considered, $g\mu_B B$ is Zeeman energy of the Mn ions in the magnetic field B ; the conduction electron is scattered from state \mathbf{k} spin ν to state $\mathbf{k}+\mathbf{q}$ spin μ by the localized spin \mathbf{S}_i of the magnetic Mn ions. J denotes the coupling between the itinerant electron and the localized spin of Mn 3d electrons. One notes that under the external magnetic field and in the internal molecular field of ferromagnetically ordered state, the band of the itinerant electrons will split, this splitting will shift the position of the conduction band with respect to the chemical potential. The spectrum of the conduction electrons with state $\mathbf{k}\sigma$ is $\epsilon_{\mathbf{k}\sigma} = \epsilon_{\mathbf{k}} - \sigma(\mu_B B + J\langle S^z \rangle)$. The scattering rate of the conduction electrons scattered by the localized spins is⁹

$$\omega = \frac{2\pi}{\hbar} \sum_m |\langle f|V|m\rangle|^2 \delta(E_f - E_m), \quad (4)$$

where $|f\rangle$ refers to the final equilibrium state and $|m\rangle$ the intermediate state of the system during the scattering process. Summing over all the intermediate states at a temperature of T , one gets

$$\omega = \frac{\pi J^2 D(0)}{\hbar} \sum_{\mathbf{k}\mathbf{q}\sigma} f_{\mathbf{k}\sigma} (1 - f_{\mathbf{k}\sigma}) f_{\mathbf{k}+\mathbf{q}\bar{\sigma}} (1 - f_{\mathbf{k}+\mathbf{q}\bar{\sigma}}) \times [\langle S_q^- S_{-q}^+ \rangle + \langle S_q^+ S_{-q}^- \rangle + 8\langle S_q^z S_{-q}^z \rangle], \quad (5)$$

where $D(0)$ is the density of states of the conduction electrons near the chemical potential, $f_{\mathbf{k}} = 1/[e^{\beta(\epsilon_{\mathbf{k}} - \epsilon_F)} + 1]$ is the Dirac-Fermi distribution function. The lifetime of the conduction electron between two scatterings is $\tau = \omega^{-1}$, and the resistivity can be obtained by the Drude formula, $\rho = m^*/ne^2\tau = m^*\omega/ne^2$, where n denotes the carrier density, m^* the effective mass of carriers. One could obtain the temperature- and field-dependent resistivity $\rho(T, B)$ as

$$\rho(T, B) = \sum_{\mathbf{q}} F(\mathbf{q}, T, B) [\langle S_q^- S_{-q}^+ \rangle + \langle S_q^+ S_{-q}^- \rangle + 8\langle S_q^z S_{-q}^z \rangle], \quad (6)$$

where the factor $F(\mathbf{q}, T, B)$

$$F(\mathbf{q}, T, B) = \frac{\pi D(0) m^* J^2}{4\hbar n e^2} \sum_{\mathbf{k}\sigma} f_{\mathbf{k}\sigma} (1 - f_{\mathbf{k}\sigma}) f_{\mathbf{k}+\mathbf{q}\bar{\sigma}} \times (1 - f_{\mathbf{k}+\mathbf{q}\bar{\sigma}}). \quad (7)$$

FIG. 2. Magnetoresistance of La-Sr-Mn-O bulks, theoretical parameters are chosen as $J=300$ K, $T_c=140$ K, $T=70$ K.

$F(\mathbf{q}, T, B)$ depends on the temperature T and the magnetic field B . Accordingly, for specific doped concentration, x , the effective mass and the concentration of carriers are fixed, the resistivity is determined by the spin-correlation functions and the factor F .

III. RESULTS

In order to obtain quantitative results, the concrete forms of the transverse and the longitudinal spin-spin correlation functions over all the temperature range and in any magnetic field are needed. However, such an exact correlation function is not available for two- and three-dimensional Heisenberg ferromagnets. In this article, the approximate forms of the longitudinal and transverse correlation functions ($T < T_c$) (Ref. 8) and the longitudinal correlation function ($T > T_c$) (Ref. 9) are adopted. The resistivity and the magnetization are measured in reduced units.

A. For three-dimension cases

We first consider the bulk material of La-R-Mn-O, the lattice constant $a=3.8$ Å, and the coordinate number z is 6. The theoretical curves are evaluated for La-Sr-Mn-O compounds.

In the three-dimension case, the order-disorder transition occurs within a narrow temperature range. When approaching the critical point T_c , the spin-spin correlation function changes dramatically from the long-range correlation to short-range one. The temperature dependence of magnetization, the resistivity and the MR in the bulk La-Sr-Mn-O with the magnetic field $B=8$ T is shown in Fig. 1, these quantities exhibit step fall when temperature (T) exceeds the Curie point T_c , which can be attributed to the weaken of the spin-spin correlation and the reduction of spin-correlated fluctuation scattering. The MR exhibits a maximum, which is similar to results of Fisher *et al.*¹⁰

The field-dependence of the MR below Curie temperature is shown in Fig. 2. The MR decreases monotonously with increasing magnetic field. The MR ratio in the bulk case is 1600% for $B=8$ T. The behavior of the MR above and below T_c does not agree with the experiment very well.¹¹ That indicates that some other scatterings are needed to be considered.

FIG. 3. Temperature dependence of magnetization and resistivity under different magnetic fields for La-Sr-Mn-O thin films where $J=500$ and $T_c=345$ K. (1) Magnetization in $B=1$ T, (2) resistivity in $B=1$ T, and (3) resistivity in $B=10$ T.

B. For two-dimension cases

In the quasi-two-dimensional systems, such as in thin films, the lattice constant is chosen to be the same as in the three-dimensional case, and the coordinate number is $z=4$. The temperature dependence of the magnetization and the resistivity in La-Sr-Mn-O thin film are shown in Fig. 3. The magnetization is calculated self-consistently under an external magnetic field $B=1$ T. Because of the reduction of the dimension, the transition temperature is broadened. The spin order-disorder transition occurs within a wide range (see Fig. 3). Correspondingly, the resistivities under different magnetic fields exhibit maxima within the transition region, since the spin-correlation scattering rate ω is very large near the transition point. When the magnetic field is increased, the resistivity peak moves to higher temperature and the maximum value is reduced (see curves 2 and 3 in Fig. 3). This could be interpreted as that a strong field aligns all spins in the systems and suppresses the correlation between spin at different sites, thus reduces the spin-correlated fluctuation scattering between the conduction electrons and the localized spins. These theoretical results agree with the experiments very well.¹⁻⁴

The field-dependence of the MR for a quasi-two-dimension system is shown in Fig. 4. One can see that the magnetoresistance also decreases monotonously with increasing field in the strong field region. This fact coincides with the experiments.¹⁻⁴ The MR ratio $\Delta R_B/R_B$ in field $B=6$ T can be as high as 1000%.

IV. DISCUSSION AND CONCLUSION

The resistivity due to the interaction Eq. (3) was studied for bulks by Fisher *et al.*¹¹ Fisher's work doesn't consider the spin-splitting of the conduction electrons caused by the external magnetic field and the internal molecular field, which may be important for the MR effect in an external magnetic field and magnetically ordered state. Our study has shown that the spin correlation scattering is essential in the thin films and should be responsible for the giant MR near T_c where the long-range or the short-range spin-spin correlations and the spin fluctuation are large.

FIG. 4. Field dependence of resistivity for La-Sr-Mn-O thin films. Theoretical parameters: $T_c=240$, $J=500$, and $T=30$ K.

From this study we can summarize several results. (a) If the measurement temperature is below or above far away from the critical point T_c , the MR change ΔR_B is small. However, the MR behaviors below and above T_c may be dramatically different since the former is dominated by the fluctuation scattering of the long-range spin-correlation, the latter is by that of short-range correlation. (b) If the critical transition range is wide, a giant MR could be observed within a wide temperature range, this property is useful for the applications. It suggests us that if we want to find a new kind of material which could be used in room temperature for magnetic recording and sensitive detect, then the Curie critical point of this material should be near the room temperature, and it should be in a low-dimension system, such as in thin film. It also indicates that in the case of magnetic multilayers, if measured temperatures near T_c , a more high giant MR may be found. Further experiments are extremely desired to verify these predictions.

Giant magnetoresistive memory effect in $\text{Nd}_{0.7}\text{Sr}_{0.3}\text{MnO}_2$ (abstract)

G. C. Xiong, Q. Li, H. L. Ju, R. L. Greene, T. Venkatesan, M. Dominguez, S. E. Lofland, and S. M. Bhagat

Department of Physics, Center of Superconductivity Research, University of Maryland, College Park, Maryland 20742-4111

A novel giant magnetoresistance memory effect has been observed in epitaxial $\text{Nd}_{0.7}\text{Sr}_{0.3}\text{MnO}_2$ thin films which have previously been found to exhibit a linear increase in conductivity on first application of a magnetic field (B). Here we reported that the conductivity of the films depends not only on the applied field but also on the magnetic history. At T well below the temperature T_p where the zero-field resistivity has a peak, the film enters a high conductivity state [$(\Delta R/R_B) > 10^3$] upon application of a magnetic field which persists even when B is reduced to zero. The original "zero" field state is not recovered until the sample is warmed to $T \sim T_p$. Surprisingly, the dc magnetization exhibits only a weak irreversibility while the magnetoconductivity is markedly hysteretic. That is, while the remanent magnetization is small the remanent magnetic resistivity is 10^{-3} times the initial zero-field-cooled resistivity. A possible explanation based on a two-component model of semiconducting matrix with embedded shunting paths of ferromagnetic material will be presented.

Systematic magnetization and ferromagnetic resonance (FMR) measurements have been performed on thin-film samples of $\text{La}_{0.67}\text{Ba}_{0.33}\text{MnO}_2$ ($T_C \sim 340$ K). It is found from the FMR data that as-grown films show broad lines whose width Γ increases to nearly 1 kOe as T reduced to 77 K. The increase roughly follows the increase in the magnetization suggesting magnetic inhomogeneity as the main cause for the rise in Γ . However, when films were properly annealed in O_2 , we obtained narrow lines ($\Gamma \sim 200$ Oe at 10 GHz). Γ was effectively independent of temperature and linearly dependent upon microwave frequency, both of which are strong signs that, we have succeeded in obtaining a *uniform, homogeneous manganite* sample. Having gotten a uniform material, we have measured the intrinsic properties of this system. © 1996 American Institute of Physics. [S0021-8979(96)51908-9]

Ferromagnetic resonance (FMR) linewidths provide a very sensitive probe of the magnetic homogeneity of a sample. The mixed manganites such as $\text{La}_{1-x}\text{Ba}_x\text{MnO}_3$, which have attracted a great deal of attention recently, are very susceptible to variations in local chemistry. Thus non-uniformity and inhomogeneity are serious concerns. We demonstrate how FMR was used to confirm magnetic homogeneity, or lack thereof, in thin film samples and discuss some of the characteristics of the nearly homogeneous films obtained by a long-anneal procedure. Here we focus on the magnetic properties, the transport properties are discussed elsewhere.¹

Films of $\text{La}_{0.67}\text{Ba}_{0.33}\text{MnO}_2$ (LBMO) were produced by pulsed-laser deposition (PLD) onto LaAlO_3 (LAO) substrates. After deposition, some of the films were annealed, at 1000 °C in an atmosphere of O_2 with a flow rate of ~ 40 cc/min for several days, and some were left as grown. The thickness of the films is 4000 Å, nominally. Rutherford back-scattering (RBS), ion-channeling and x-ray diffraction showed that the films had very good crystallinity. Direct current magnetization was measured with a quantum interference device (SQUID) magnetometer in fields of 0–10 kOe applied parallel to the film plane.

FMR measurements were performed at 3.5, 10, 22, and 36 GHz, using conventional modulation and lock-in detection techniques² over a temperature range of 77–360 K. Data were taken in both the parallel (H_{\parallel} film plane) and perpendicular (H_{\perp} film plane) geometries.

It is well known that ferromagnetic resonance lines are well described by the Landau–Lifshitz–Gilbert equation.³ For large linewidths, a correction must be applied to determine the true resonance fields.⁴ For the narrow lines observed here, detailed lineshape calculations³ based on the Landau–Lifshitz–Gilbert equation justify the use of the Kittel resonance equations

$$\frac{\omega}{\gamma} = [H_{\parallel}(H_{\parallel} + 4\pi M_{\text{eff}})]^{1/2}, \quad (1a)$$

$$\frac{\omega}{\gamma} = H_{\perp} - 4\pi M_{\text{eff}}, \quad (1b)$$

where ω is the microwave frequency, $\gamma = (g\mu_B/\hbar)$ the gyro-magnetic ratio, H_{\parallel} and H_{\perp} the resonance fields in the parallel and perpendicular geometries, respectively, and M_{eff} the effective magnetization. H_{\parallel} , H_{\perp} , and M_{eff} may be influenced by the anisotropy torques, if any.

FMR data from as-grown films are rather hard to interpret meaningfully. At 300 K, the resonance is quite sharp, the peak-to-peak linewidth Γ_{pp} being 0.2 kOe and Γ_{pp} increases rapidly when T is lowered (squares, Fig. 1). At low temperatures several lines besides the main resonance appear, especially in the perpendicular geometry. This is a clear indication of inhomogeneity. Although the x-ray and RBS data point to a homogeneous material, the FMR clearly suggests otherwise. This sample we designate LBMO-*I* where *I* stands for inhomogeneous.

Whereas it is not fruitful to offer quantitative explanations for the T variation of the inhomogeneously broadened linewidths, it is useful to note that the increase in Γ_{pp} follows closely that of $4\pi M_{\text{eff}}(T)$ (circles, Fig. 1) obtained from Eq. (1a) using $g=2.00$. This fact suggests that the observed $4\pi M$ is an average value and that a distribution of M values should be invoked to account for the linewidth data.

FIG. 1. Measured linewidth Γ_{pp} (squares) vs T for LBMO-*I**. The full line is a guide to the eye. The dashed line represents the expected T dependence of Γ_{pp} for a uniform ferromagnet. $4\pi M_{\text{eff}}$ (circles) vs T for LBMO-*I* from 10-GHz data. Notice that Γ_{pp} follows $4\pi M_{\text{eff}}$.

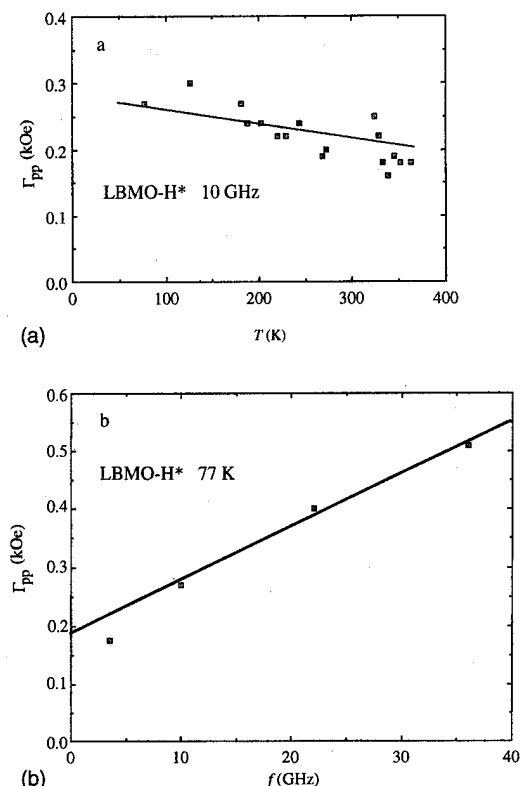

FIG. 2. (a) Γ_{pp} vs T for LBMO- H^* at 10 GHz. The line is a guide to the eye. Γ_{pp} is nearly independent of T , as expected for a homogeneous ferromagnet. (b) Γ_{pp} vs f for LBMO- H^* . The linear dependence of Γ_{pp} is as expected of a uniform ferromagnet, although the nonzero intercept suggests some remaining inhomogeneity.

In contrast to that of as-grown films, the FMR response of highly annealed films is quite satisfactory. The T dependence of Γ_{pp} for the parallel geometry is displayed in Fig. 2(a) for 10 GHz, and one notes that Γ_{pp} is effectively independent of T , as expected for a simple ferromagnet.⁵ As a further check of the validity of this interpretation, consider the frequency (f) dependence of Γ_{pp} at 77 K. As seen in Fig. 2(b), Γ_{pp} increases linearly with f . However, as also found in amorphous ferromagnets,⁴ extrapolation of Γ_{pp} has a nonzero value at $f=0$, indicative of a residual magnetic

FIG. 3. $4\pi M_{\text{eff}}$ and $4\pi M$ vs T for LBMO- H^* derived from 10-GHz FMR data and SQUID magnetometry, respectively. The difference between $4\pi M_{\text{eff}}$ and $4\pi M$ is ascribed to strains in the film.

FIG. 4. Resonance field H_θ vs θ for LBMO- H^* at 77 K and 10 GHz. The full line is a solution to the resonance equations as a function of θ for $4\pi M = 8.15$ kOe and $g = 2.00$. The inset is Γ_{pp} vs θ . Γ_{pp} is largest near the point where $dH_\theta/d\theta$ is a maximum.

inhomogeneity within the sample. This film we designate LBMO- H^* , where H^* stands for nearly homogeneous.

Now that we have a fairly uniform sample we can measure its intrinsic magnetic properties. Consider the value of the effective magnetization $4\pi M_{\text{eff}}$ (squares, Fig. 3) obtained from FMR. This is to be compared with the SQUID data (triangles, Fig. 3). It is clear that the difference is ~ 1 kOe, increasing somewhat with reducing T . Most likely, this arises from anisotropy caused by strains and a non-zero magnetostriction in the films.

Figure 4 shows the variation of the resonance field H_θ and linewidth (inset) as the applied field is rotated from the parallel ($\theta=0^\circ$) to the perpendicular configuration at 77 K. The full line was calculated using a straightforward generalization of the Kittel equations with $4\pi M_{\text{eff}} = 8.15$ kOe and $g = 2.00$. The close agreement shows that, in this film, the anisotropy is uniaxial with the symmetry (hard) axis being normal to the film plane. The variation of Γ_{pp} with θ serves as a consistency check on the validity of the resonance equations. $\Gamma_{pp}(\theta)$ should be maximal where $[dH_\theta(\theta)/d\theta]$ is largest, as we observe.

Writing $(4\pi M_{\text{eff}} - 4\pi M) = 2K_u/M$, one obtains the T variation of the anisotropy constant K_u shown in Fig. 5. The magnitude of K_u is not unreasonable. Simple theory⁶ would give $K_u \sim (3/2)\lambda_m\sigma$ where λ_m is the magnetostriction constant and σ the stress in the film. A λ_m value of 10^{-5} seems credible, giving $\sigma \sim 10^{10}$ erg/cm³. This implies strains of

FIG. 5. Anisotropy constant K_u vs T derived from $4\pi M_{\text{eff}}$ and $4\pi M$. The line is a guide to the eye. The nonmonotonic behavior may be the result of magnetostriction.

$\sim 10^{-2}$, which are not unusual for a film grown on a substrate with a lattice mismatch of $\sim 3\%$. Also, Perekalina *et al.*⁷ measure $K_u \sim 10^5$ erg/cm³ in $\text{La}_{1-x}(\text{Sr, Pb})_x\text{MnO}_{3+\gamma}$ crystals ($x=0.1$ and 0.3) by torque measurements. The T dependence of K_u is not understood at this time, although nonmonotonic T dependences of magnetostriction have been reported.⁸ It would be surprising if strain-induced fields did not also contribute to the line broadening. Part of the intercept observed in Fig. 2(b) could arise from this source.

In conclusion, it has been found that as-grown thin-film samples of $\text{La}_{0.67}\text{Ba}_{0.33}\text{MnO}_z$, which appear to be quite uniform by other techniques, show wide FMR lines, suggestive of sizeable magnetic inhomogeneity. Using a proper annealing treatment of thin films, behavior symptomatic of a uniform, homogeneous ferromagnet was observed in both the frequency and temperature dependence of the FMR linewidths. The present FMR linewidths are the narrowest observed in any giant magnetoresistance manganite system. It seems reasonable to claim that the heat treatment used here,

although not fully optimized, yields the most homogeneous manganite films studied so far. This can be expected to become a benchmark for further work on these interesting systems.

We thank M. A. Manheimer for use of the 3.5 GHz spectrometer and M. Dominquez and R. P. Sharma for a fruitful discussion.

Role of epitaxy and polycrystallinity in the magnetoresistance and magnetization of $\text{La}_{0.8}\text{Sr}_{0.2}\text{MnO}_3$ thin films

Kannan M. Krishnan, A. R. Modak, and C. A. Lucas

Materials Sciences Division, Lawrence Berkeley National Laboratory, Berkeley, California 94720

$\text{La}_{0.8}\text{Sr}_{0.2}\text{MnO}_3$ thin films were simultaneously deposited by pulsed laser ablation on silicon (Si) and LaAlO_3 (LAO) substrates. Films on Si were polycrystalline while those on LAO were (100) epitaxial with an in-plane correlation length of ≈ 10 nm. The magnetization and magnetoresistance behavior of these two films were significantly different. Both films exhibit antiferromagnetic-ferromagnetic transitions—at different temperatures [180 K (LAO); 230 K (Si)]—and their magnetic moments at 10 K were significantly different (Si—0.0035 emu; LAO—0.0022 emu). However, both films showed significant high field slope in magnetization at 10 K. Significant fractions of both films remain antiferromagnetic at low temperatures and hence net susceptibilities, dependent on the direction of the applied magnetic field, are different for the epitaxial (LAO) and randomly oriented polycrystalline (Si) films. The magnetoresistance peak, corresponding to the semiconductor-metal transition is observed at 170 and 130 K for the epitaxial (LAO) and polycrystalline (Si) films, respectively. Moreover, their resistance values are two orders of magnitude different (Si—M Ω hms; LAO—K Ω hms). These properties can be interpreted in terms of the major role of grain boundaries in determining the scattering as well as possible differences in O_2 stoichiometry. © 1996 American Institute of Physics. INTRODUCTION

The magnetic and electronic transport properties of alkaline earth substituted manganese oxides, $\text{La}_{1-x}\text{A}_x\text{MnO}_3$ (A = Ca, Sr, or Ba), with perovskite structure are quite well known.^{1,2} In particular, for $0.1 < x < 0.5$, they order ferromagnetically near room temperature and the mixed $\text{Mn}^{3+}/\text{Mn}^{4+}$ content resulting from divalent substitution leads to quasimetallic conductivity. The fundamental mechanism governing their galvanomagnetic properties and magnetization behavior is, as yet, not clearly understood—traditionally, treatments have focused on the “double exchange” interaction³ whilst more recently, explanations involving polaron effects due to a strong electron-phonon coupling arising from a Jahn-Teller splitting of the Mn^{3+} ion have been proposed.⁴ On the other hand, the very large negative magnetoresistance observed in these materials^{5–7} has attracted much recent attention because of their potential application in information storage and other field sensing devices. It is claimed⁷ that these properties are dependent on the optimization of the conditions of growth and annealing, composition, oxidation state, epitaxy, and the overall microstructure. In order to address these latter issues we have grown $\text{La}_{0.8}\text{Sr}_{0.2}\text{MnO}_3$ (LSMO) films by laser ablation simultaneously on LaAlO_3 (LAO) and silicon (Si) substrates, characterized their crystallography and measured their magnetic/transport properties.

EXPERIMENTAL DETAILS

LSMO thin films were synthesized by pulsed laser deposition using a 248 nm KrF excimer laser (Lambda Physik, Lextra 200) with a 30 ns pulse width and output energy of 400 mJ. The laser was operated at 3 Hz for 15 min producing

films ~ 2000 Å thick. A sintered $\text{La}_{0.8}\text{Sr}_{0.2}\text{MnO}_3$ target was used. The ejected plume of material was deposited simultaneously onto polished LaAlO_3 [100] and Si [100] (with native oxide) substrates maintained at 675 °C. The base pressure in the chamber was 2×10^{-6} Torr. During the deposition the oxygen pressure in the vacuum chamber was maintained at 100 mTorr by flowing oxygen at 50–70 sccm. After deposition, the films were cooled to room temperature at 5 °C/min in an oxygen pressure between 500 and 600 Torr.

X-ray diffraction measurements were made using a four-circle Huber diffractometer based on a 12 kW Rigaku rotating-anode source. $\text{Cu } K_{\alpha 1}$ x-rays were selected and collimated using a graphite monochromator crystal, scattered from the sample and then detected by a scintillation counter after passing through a resolution-defining slit. In this mode of operation the instrumental resolution is relatively poor ($\sim 1 \times 10^{-2}$ Å⁻¹) but the incident x-ray intensity is higher than in a high resolution mode.⁸

Magnetization and resistance measurements were performed in a Quantum Design SQUID based magnetometer system. A modified sample holder equipped with electrical leads was used for the resistance measurements. The leads were attached using pressed indium contacts. In all measurements, the field was applied in the plane of the film and the current was applied parallel to the field.

RESULTS AND DISCUSSION

For the sample grown on the Si substrate, the dominant feature in a θ -2 θ x-ray scan was the (004) Si Bragg reflection and this was accompanied by several other weak peaks which could be indexed to the perovskite film. As the film

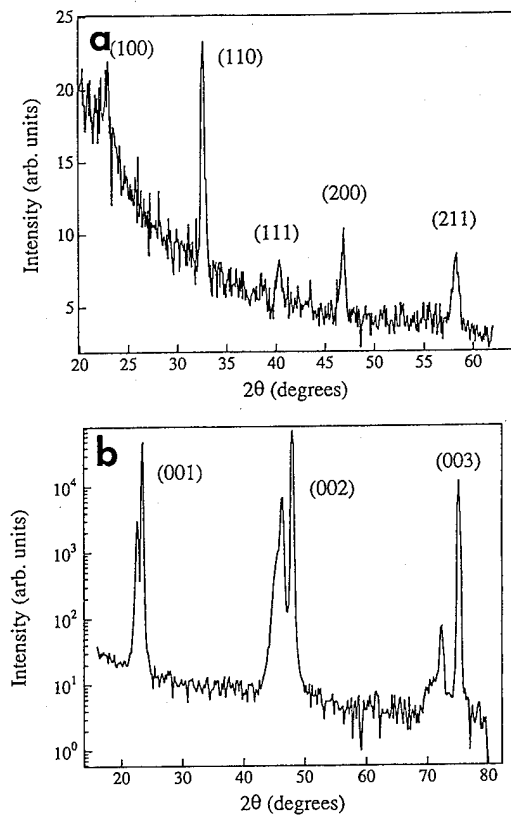

FIG. 1. (a) 2θ x-ray scan at fixed θ angle (8°) for the LSMO (80/20) film grown on a Si substrate. (b) $\theta-2\theta$ scan for the LSMO (80/20) film grown on a LaAlO_3 substrate.

Bragg peaks showed no specific orientation dependence in rocking scans (i.e., the film is polycrystalline), a 2θ scan was performed at a fixed θ angle (8°) to remove the Si Bragg reflection. The result is shown in Fig. 1(a). Assuming a cubic structure for the perovskite film allows the peaks to be indexed as shown in Fig. 1, and the lattice constant is determined to be $a = 3.88 \pm 0.05 \text{ \AA}$.

Figure 1(b) shows a $\theta-2\theta$ scan for the film grown on the LaAlO_3 substrate ($a = 3.78 \text{ \AA}$). Again the peaks are indexed according to the cubic notation. The two peaks at each position correspond to the substrate (higher intensity) and the perovskite film. A rocking scan through the LaAlO_3 peak gives a full-width-half-maximum (FWHM) of $\sim 0.18^\circ$ which is merely the limit of the instrumental resolution. This compares to a FWHM of the perovskite peak of 1.1° . The position of the perovskite peak corresponds to a cubic surface-normal lattice constant, $c = 3.92 \text{ \AA}$. Measurement of in-plane Bragg reflections, e.g., (111), gave a smaller lattice mismatch and implies that there is some in-plane lattice matching causing a tetragonal distortion in the film. In Fig. 2 there also appears to be a shoulder on the low angle side of the film peak. This feature is an order of magnitude smaller than the principal peak and may be due to regions of the film that are perfectly lattice matched, in-plane to the substrate, thus leading to a larger tetragonal distortion. Finally a rocking scan through the in-plane (200) perovskite Bragg reflection gave a Lorentzian lineshape with a FWHM of 1.32° . This corresponds to an in-plane correlation length of $\sim 100 \text{ \AA}$. Trans-

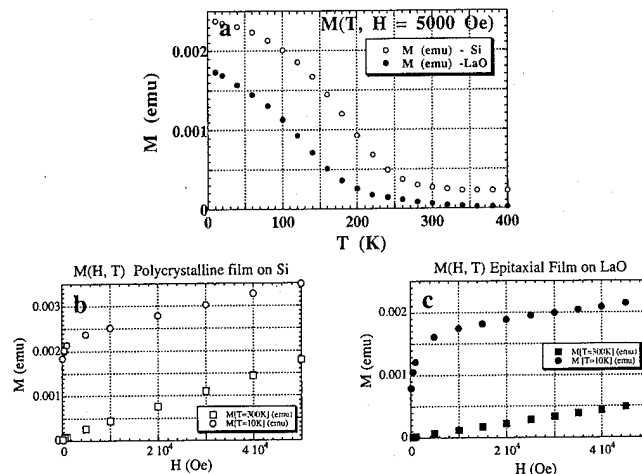

FIG. 2. (a) $M(T, H = 5 \text{ kOe})$ for polycrystalline (Si) and epitaxial (LAO) films. $M(H)$ behavior at $T = 10 \text{ K}$ and 300 K for the films are shown in (b) and (c).

mission electron microscopy (TEM) observations are also in progress to corroborate these deductions.

A comparison of the magnetic moments of the two films, that have identical volumes (since the films have identical area as well as thickness), in an applied field of 5000 Oe as a function of temperature is shown in Fig. 2(a). The ferromagnetic transition temperatures are $\sim T_c = 180 \text{ K}$ and $T_c = 230 \text{ K}$ for the films deposited on LaAlO_3 and Si, respectively. Both films show a room temperature $M(H)$ that is linear with applied field consistent with antiferromagnetism [Figs. 2(b) and 2(c)]. However, the magnetic moment at 5 T for the polycrystalline film ($\approx 0.0035 \text{ emu}$) is higher than that observed for the epitaxial film ($\approx 0.0022 \text{ emu}$). Both films showed a significant high field slope at 10 K even at applied fields as high as 5 T .

The temperature and field dependent resistance values of the two films were quite different. The overall resistance of the polycrystalline films on Si was 2–3 orders of magnitude greater than that of the single crystal film on LaAlO_3 . The resistance of the polycrystalline film increased monotonically with decreasing temperature except for a small bump observed around 130 K [Fig. 3(a)]. At roughly the same temperature, a rather broad peak in the magnetoresistance was observed: the peak magnetoresistance was 125% in a field of 5 T . The zero field resistance of the single crystal film peaked (at 185 K) more sharply than the polycrystalline films, and dropped as temperature decreased further indicating a semiconductor to metal transition [Fig. 3(b)]. In this case, the peak in magnetoresistance is correlated reasonably well with the onset of the magnetic transition: the peak magnetoresistance of the single crystal was 140% in a field of 5 T , at a temperature of 170 K , which is slightly below the magnetic transition.

The distinct difference in the behavior of the polycrystalline and epitaxial (LSMO) films of the same composition (except for oxygen stoichiometry) and thickness is evidence of the significant dependence of the magnetotransport properties on the nature of crystallinity. The magnetic properties

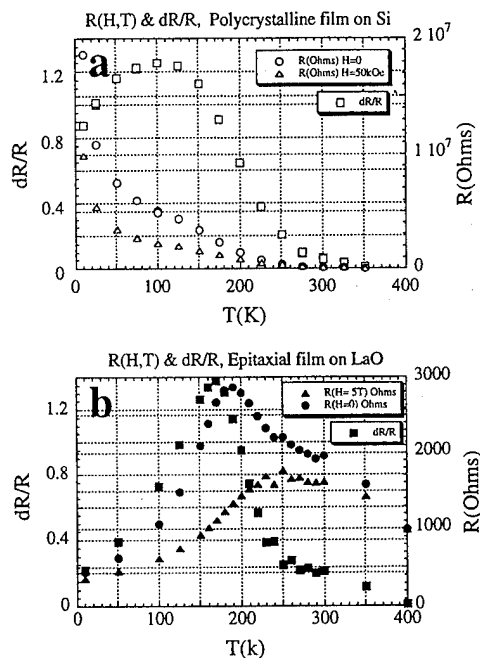

FIG. 3. $R(H=0)$, $R(H=5\text{ T})$, and $[R(0) - R(5\text{ T})]/R(0)$ vs T for the polycrystalline (Si) films (a) and epitaxial (LAO) films (b).

can then be rationalized in relation to the microstructure.

The high-field susceptibility of the polycrystalline LSMO films in the antiferromagnetic state (at room temperature) is higher than in the epitaxial films. This fact may be understood in terms of the crystal structure. It is known that in single crystal LSMO alternate (001) planes are antiferromagnetically ordered.² In each (001) plane the moments are ferromagnetically ordered along either the (010) or the (100) directions. Hence for the epitaxial film, with the field applied in the plane of the film, the measured susceptibility is: $\chi_{\text{epitaxial}} = 1/2 (\chi_{\parallel} + \chi_{\perp})$, where χ_{\parallel} and χ_{\perp} are the susceptibilities parallel and perpendicular to the spin alignment. This assumes that the distribution of domains corresponding to the two possible orientations is statistically equivalent, and the crystal anisotropy is large enough so that the domains do not flip at low field and align perpendicular to the applied field. At the same time, for the polycrystalline film, the measured susceptibility is $\chi_{\text{polycrystalline}} = 1/3 (\chi_{\parallel} + 2\chi_{\perp})$ assuming random orientation.⁹ Below the Neel temperature it is reasonable to assume that χ_{\parallel} decreases with decreasing temperature and χ_{\perp} remains constant, and that in general $\chi_{\parallel} < \chi_{\perp}$. Thus the polycrystalline film is expected to have a higher measured susceptibility than the (100) epitaxial film. Our measurements show a $\chi_{\parallel} \approx 5.3 \times 10^{-3}$ and $\chi_{\perp} \approx 3.6 \times 10^{-3}$ at room temperature.

Both the Curie temperature and the ferromagnetic magnetization of the epitaxial film are lower than those of the polycrystal implying that the ferromagnetic moment per Mn atom is smaller in the single crystal than in the polycrystal. In these films the relative atomic fraction of both Sr and O affect the tetravalent Mn content. Further, the change in the ferromagnetic moment per Mn atom with the fraction of tetravalent Mn is particularly large close to 20% Mn^{4+} , which would be expected in the composition corresponding to 20

at % Sr^{2+} . Since the total number of La, Sr, and Mn atoms in the two films are nominally equal, the difference in the moments could arise mainly from differences in oxygen stoichiometry. The interdiffusion of oxygen would be much faster along grain boundaries than in the bulk and hence, the polycrystal would have a higher equilibrium oxygen content than the single crystal. Future (EELS) measurements may help to clarify the issue relating to the relative oxygen stoichiometries in the two films.

The absolute resistance of the polycrystalline film is higher than the epitaxial film due to the additional scattering from defects and grain boundaries as well as the differences in oxygen stoichiometry. This is to be expected considering the small grain size observed in the polycrystalline films (0.1–0.2 μm) from TEM studies.¹⁰ The slightly larger magnetoresistance of the epitaxial film as compared to the polycrystalline film, however, is not yet completely understood. Both the proposed mechanisms, i.e., double exchange and polaron effects, would be significantly affected by structural irregularities at grain boundaries leading to a reduction in intergranular conductivity. The effect of grain boundaries would be particularly significant in these materials due to their uniquely coupled magnetic and conductive properties. Note that the magnitude of the magnetoresistance of polycrystalline films is similar to that observed for the epitaxial films although the resistance versus temperature curves show a largely insulatorlike behavior (except for the very small bump at 130 K). Only the temperature dependence of the MR is significantly affected. This indicates that although the semiconductor–metal transition is closely associated with the MR effect, it does not influence the magnitude significantly. The polycrystallinity increases the resistance of the film while maintaining the percentage magnetoresistance.

Overall, the results confirm the important role of the microstructure in determining the properties of LSMO films and suggest the need to make measurements on well defined grain boundaries, e.g., films grown on bicrystal substrates. Such experiments would permit an understanding of the influence of grain boundaries on the double exchange interactions, in addition to magnetoresistance properties.

Magnetic exchange and charge transfer in mixed-valence manganites and cuprates

Gerald F. Dionne

Lincoln Laboratory, Massachusetts Institute of Technology, Lexington, Massachusetts 02173

Metallic resistivity occurs at cryogenic temperatures in insulators with small carrier trap energies, e.g., superconducting cuprates. A similar metallic regime has been reported for the lanthanide (RE) manganites $(\text{RE}_{1-x}^{3+}\text{A}_x^{2+})\text{MnO}_3$. To interpret the anomalous resistivity ρ as a function of temperature and magnetic field in these compounds, a model constructed from the relation for mobility activated semiconduction and the Brillouin–Weiss theory of ferromagnetism has been developed. The resistivity maximum occurs at the susceptibility peak slightly above the Curie temperature T_C and its magnitude is related to the hopping electron trap energy E_{hop} by $\exp(E_{\text{hop}}/kT_C)$. Where $T < T_C$, ρ is metallic because E_{hop} is small due to the collinear polarization of spins. For $T \geq T_C$, E_{hop} increases to a value ~ 0.1 eV equal to the decrease in stabilization energy of the transfer electrons caused by the transition from spin alignment to disorder. The magnetoresistance sensitivity $d\rho/dH$ at $T = T_C$ is controlled by T_C through $(1/T_C)\exp(E_{\text{hop}}/kT_C)$. The relative sensitivity $(1/\rho)d\rho/dH$, however, is proportional to $1/T_C^2$. These results also reinforce the concept that metallic resistivity in the superconducting cuprates occurs because of the frustration of antiferromagnetism. © 1996 American Institute of Physics. I. INTRODUCTION

Recent observations of anomalous reductions in electrical resistivity of lanthanide perovskite $(\text{RE}^{3+}\text{A}^{2+})\text{MnO}_3$ films in strong magnetic fields¹ have prompted a reexamination of the seminal work on the properties of these mixed-valence manganites. Original magnetic studies were reported by Jonker and Van Santen in 1950.² A follow-up note³ reported the characteristic peak in resistivity at the Curie temperature, similar to that observed in the films.

In this article, the magnetic and electronic data are discussed in terms of the conventional theories and a phenomenological model of magnetoresistance is developed and used to interpret reported measurements. To place the low temperature metallic electrical behavior in a broader context, the charge transfer mechanisms of the $\text{Mn}^{3+} \leftrightarrow \text{Mn}^{4+} + e^-$ combination are compared with those of $\text{Cu}^{2+} \leftrightarrow \text{Cu}^{3+} + e^-$ in the p -type high- T_C superconducting cuprates.⁴

II. MAGNETIC PROPERTIES OF $(\text{RE}^{3+}\text{A}^{2+})\text{MnO}_3$

In the generic $(\text{RE}^{3+}\text{A}^{2+})\text{MnO}_3$ system, three oxidation states of Mn can occur, offering a variety of 180° superexchange interactions. For the cubic octahedral oxygen coordination, crystal-field effects dictate that the t_{2g} orbital states are of lower energy and are half-filled to satisfy the Hund's rule spin polarization requirement for each of $\text{Mn}^{2+}(d^5)$, $\text{Mn}^{3+}(d^4)$, and $\text{Mn}^{4+}(d^3)$. For all combinations of ionic pairs, the t_{2g} electrons provide weak antiferromagnetism via π bonding through the O^{2-} anions, e.g., $\text{Mn}^{4+}-\text{O}^{2-}-\text{Mn}^{4+}$. For the Mn^{2+} and Mn^{3+} ions, the exchange is determined more by the stronger σ -bonding e_g states. A single electron in the e_g states (Mn^{3+} case) can be stabilized by a static Jahn–Teller (JT) orthorhombic distortion that splits energy levels as shown in Fig. 1. Exchange couplings expected for the various ion combinations are well documented.⁵

According to Curie temperature T_C data² for $(\text{RE}_{1-x}^{3+}\text{A}_x^{2+})\text{Mn}_{1-x}\text{Mn}_x\text{O}_3$, ferromagnetism dominates in

the regime up to $x=0.5$, with a peak near $x=0.3$. As Mn^{4+} ions are introduced, parallel spin alignments occur through a combination of factors: (i) the $\text{Mn}^{3+}-\text{O}^{2-}-\text{Mn}^{4+}$ couplings produce ferromagnetism through charge transfer between half-filled and empty orbital states, and (ii) the anticipated antiferromagnetism from the collective $\text{Mn}^{3+}-\text{O}^{2-}-\text{Mn}^{3+}$ couplings in a static JT effect are converted to ferromagnetism possibly by the vibronic-induced JT effect proposed by Goodenough *et al.*⁶ that blurs the e_g bands and allows the Mn^{3+} e_g electrons to transfer into empty orbital states.

For a random distribution of Mn^{4+} ions, the exchange energy E_{ex} of a spin \mathbf{S}_i surrounded by z spins \mathbf{S}_j is given by the Hamiltonian $\mathcal{H}_{\text{ex}} = 2\sum_j J_{ij}\mathbf{S}_i \cdot \mathbf{S}_j = 2zJS^2 \cos \theta$, and

$$E_{\text{ex}} = 2z[J_{33}S_3^2(1-x)^2 + 2J_{34}S_3S_4x(1-x) + J_{44}S_4^2x^2]\cos \theta, \quad (1)$$

where J is the average J_{ij} coefficient; the average $S = (1-x)S_3 + xS_4$, and θ is the average angle between adjacent spins. The variation in E_{ex} with x may be inferred

FIG. 1. Crystal-field splittings and ground-state orbital occupancies of Mn and Cu ions in orthorhombically distorted oxygen octahedra. Delocalization exchange with ferromagnetic spin polarization are indicated.

FIG. 2. Curves of B_S and ΔB_S vs T for $H=0$ and 10 T and $T_C=300$ K.

directly from the T_C data,² which register a peak above 300 K at $x \approx 0.3$. An empirical model⁷ is used to sort out the contributions of the individual terms in Eq. (1). To relate E_{ex} to T_C we employ the standard expression $kT_C = 2zJS(S+1)/3 = E_{ex}(S+1)/3S$. Calculations based on Eq. (1) were scaled to fit $kT_C = 0.025$ eV ($T_C = 300$ K) with a maximum at $x = 0.3$. From this exercise, J_{33} peaks at 0.0022, while $J_{34} = 0.0030$, and $J_{44} = -0.00074$ eV. It is therefore concluded that the relative importance of the terms of Eq. (1) is weighted towards the charge transfer J_{34} component.

The temperature dependence of the magnetic moment per mole $M(T)$ may be described by the Brillouin-Weiss molecular field theory which models the degree of spin collinearity, i.e., $\cos \theta$, by a Brillouin function $B_S(y)$ according to $M(T) = M(0)B_S(y)$, where $M(0) = g\mu_B S \mathcal{N}$, \mathcal{N} is Avogadro's number, and $y = E_{ex}/kT$. In a magnetic field H , $E_{ex} = g\mu_B S(H_{ex} + H)$, where g is the gyromagnetic ratio ($=2$), μ_B is the Bohr magneton, and $H_{ex} = NM$,⁷ with N the molecular field coefficient in mol/cm³. N is related to the exchange constant J (in ergs) through $N = 2zJ/g^2\mu_B^2\mathcal{N}$. For $T_C = 300$ K, B_S and ΔB_S are calculated by means of a numerical iterative procedure and plotted as a function of T for H values of 0 and 10 T in Fig. 2.

An alternative approach that allows the use of the $B_{1/2}$ function is to ignore the Russell-Saunders rule and to sum the exchange contributions from uncoupled spins. In this case, $s = 1/2$ and $JS^2 \cos \approx J^i S^2 \cos$, where J^i is the resultant exchange constant from the orbitals of the individual spins.

III. MAGNETORESISTIVE PROPERTIES OF $(\text{RE}^{3+}\text{A}^{2+})\text{MnO}_3$

The electrical conductivity of mixed-valence oxides obeys the standard relation with activated mobility,^{8,9} where $\sigma = ne(eD/kT)\exp(-E_{hop}/kT)$. The factor (eD/kT) is the Einstein diffusion mobility, n is the carrier density, and D the diffusion constant which equals the ratio of the square of the hop distance to the carrier lifetime d^2/τ . In previous studies of the normal state of the cuprate superconductors,^{10,11} this relation was refined and expressed as a resistivity:

$$\rho = C(kT)[(1-x)/x]\exp(E_{hop}/kT), \quad (2)$$

FIG. 3. Comparison of theory with experiment for ρ vs T (data of Ref. 14). The $B_{1/2}$ model was used with $N = 719$ mol/cm³.

where the effective number of carriers per formula unit $x(1-x) = nV$, V is the volume of a formula unit ($\sim a^3$) based on lattice parameter a ($=4$ Å), and $C = V/e^2 d_{min}^2 \nu_{hop}$. The hopping frequency $\nu_{hop} (= 1/\tau)$ is equated to the Debye frequency $\nu_D = (k/h)\Theta_D \approx 5 \times 10^{12}$ Hz for a Debye temperature $\Theta_D \approx 250$ K. The $(1-x)$ factor in the numerator of Eq. (2) arises from a correction to the effective hop distance d ($\propto a$) which increases with x according to $d_{min}/(1-x)$. By Eq. (2), ρ passes through a minimum at $T = E_{hop}/k$ and assumes a metallic slope that approaches the linear function $C(kT)[(1-x)/x]$.

The principal source of the activation energy E_{hop} is the reduction in stabilization energy^{11,12} of the electron carrier in the e_g orbitals that covalently link the Mn^{3+} and Mn^{4+} ions. This loss in binding energy represents the additional (thermal) energy required to effect the carrier transfer and occurs because of spin canting. Since B_S represents the z -axis projection of spins within a cone of half-angle θ , $(1-B_S)$ approximates the fractional loss in binding energy as a function of temperature and magnetic field.

The activation energy may then be expressed as $E_{hop} = E_{hop}^0 + E_{hop}^{ex}(1-B_S)$, where E_{hop}^0 is the trap energy from electrostatic and elastic factors (typically <0.01 eV for the high- T_C cuprates⁴), and E_{hop}^{ex} is the exchange contribution that reaches its full value at $T \geq T_C$.⁷ For the manganite system, $E_{hop}^{ex} \approx 0.1$ eV. This estimate for E_{hop}^{ex} is justified by equating $E_{hop}^{ex} \approx 2zJ_{34}S_3S_4 = 0.106$ eV for $z = 6$, $J_{34} = 0.0030$ eV, $S_3 = 2$, and $S_4 = 3/2$.

In Fig. 3, ρ vs T data of Li *et al.*¹³ for a composition estimated as $(\text{La}_{0.77}^{3+}\text{Ca}_{0.23}^{2+})\text{MnO}_3$ subjected to H fields of 0, 1, 3, 5, and 14 T are fitted by curves generated from Eq. (2), employing in this case the $s = 1/2$ approximation which provided a slightly better fit to the data than that obtained with the average spin model.⁷ Except for the $H = 0$ curve, which did not reach its full peak probably due to the inhomogeneously broadened tail of the M vs T curve, theory and data agree quite closely. For these and all subsequent computations, $C = 6$ mOhm cm/eV, $E_{hop}^0 = 0.004$ eV, and $E_{hop}^{ex} = 0.1$ eV.

Since E_{hop}^{ex} is a constant of the transfer ions, the peaks of ρ at $H = 0$ should theoretically touch the $(kT)\exp(E_{hop}/kT)$ envelope at the appropriate T_C values. This is confirmed by the average spin model calculations in Fig. 4. From these results, the sharp increase in ρ at T_C is enhanced by almost

FIG. 4. Curves of ρ vs T for materials with $T_C=100, 200$, and 300 K, computed from the B_S model. Numerical results are listed in Table I.

four orders of magnitude between 300 and 100 K. The ρ_{\max} ($H=0$) values listed in Table I are in general agreement with data reported in the literature, which are typically $\sim 10^2$ Ω cm at $T_C=100$ K.

Consistent with the behavior of ρ , $d\rho/dH$ at $T=T_C$ is shown to be proportional to $(1/T_C)\exp(E_{\text{hop}}/kT_C)$ and

$$(1/\rho)d\rho/dH = -g\mu_B S(S+1)E_{\text{hop}}^{\text{ex}} \mathcal{F}/3(kT_C)^2, \quad (3)$$

where \mathcal{F} is a Lorentzian-type broadening function that accounts for the paramagnetic tail at $T>T_C$.⁷ In the ideal limit as $H\rightarrow 0$, Eq. (3) states that $(1/\rho)d\rho/dH$ is inversely proportional to T_C^2 . This dependence is suggested by the computed values listed in Table I for $T=T_C$ and $dH=1$ Oe.

IV. $\text{Mn}^{3+(4+)}$ AND $\text{Cu}^{2+(3+)}$ ELECTRON TRANSFER

Metallic resistivity in transition-metal oxides also occurs in situations where one of the transfer ions is in a zero-spin state.¹¹ Unlike the $\text{Mn}^{3+}-\text{O}^{2-}-\text{Mn}^{4+}$ case where ferromagnetic spin polarization removes the exchange trap, however, $E_{\text{hop}}^{\text{ex}}$ is absent from systems with $S=0$ ions because there are no internal polarization requirements. In addition, charge transfer from these mobile nonmagnetic cations causes breakdowns of the regional antiferromagnetic couplings and can eventually reduce the Néel temperature T_N to zero.¹²

TABLE I. Parameter values at $T=T_C$ from Fig. 4.

T_C (K)	x	N (mol/cm ³)	ρ_{\max} ($H=0$) (Ω cm)	$(1/\rho)d\rho/dH$ ($dH=1$ Oe) (Oe) ⁻¹
77	0.04	26	4770	-4.7×10^{-3}
100	0.05	34	145	-3×10^{-3}
200	0.15	71	0.233	-1×10^{-3}
300	0.30	114	0.020	-2×10^{-4}

The most remarkable of these situations is seen in the p -type metallic conductivity of $\text{Cu}^{2+}-\text{O}^{2-}-\text{Cu}^{3+}$ couplings in the perovskite structure. For the Cu^{3+} ion, the $S=0$ state arises from a low-spin configuration (see Fig. 1) that occurs because of a large splitting of the e_g doublet.¹⁴ Here the splitting of $d_{x^2-y^2}$ and d_{z^2} occurs more from the pronounced tetragonal/orthorhombic symmetry of the layered perovskites than from the JT effect that is required to create the splitting in the manganites. The influence of antiferromagnetic exchange on the $\text{Cu}^{2+(3+)}$ conductivity is to deter the formation of large polarons that are necessary for the coherent activationless charge transfer of superconductivity. The presence of only 5% of zero-spin Cu^{3+} is sufficient to frustrate the antiferromagnetic ordering and create the metallic phase that allows the onset of superconductivity (the Néel temperature T_N and $T_C=0$ condition).^{11,12}

V. DISCUSSION AND CONCLUSIONS

The principal insights gained from the magnetoresistance analysis are the following.

- (1) The magnetic condition may be unique to Mn cations covalently linked in octahedral sites with 180° bonds.
- (2) The resistivity maximum $\rho_{\max} \sim (kT_C)\exp(E_{\text{hop}}/kT_C)$ at $H=0$ and occurs at the susceptibility peak slightly above $T=T_C$.
- (3) The maximum of $d\rho/dH$ occurs at $T=T_C$ and is proportional to $(1/T_C)\exp(E_{\text{hop}}/kT_C)$.
- (4) The maximum of $(1/\rho)d\rho/dH$ occurs at $T=T_C$ and is proportional to $1/T_C^2$.
- (5) $E_{\text{hop}}^{\text{ex}}$ is fixed by the local exchange energy $2zJ_{34}S_3S_4$ and is estimated from theory and experiment at 0.1 eV.
- (6) $E_{\text{hop}}^{\text{ex}}/kT_C \approx 6J_{34}S_3S_4/JS(S+1)$ and is therefore dependent mainly on the exchange energy of the individual $\text{Mn}^{3+}-\text{O}^{2-}-\text{Mn}^{4+}$ couplings.

Correlation between magnetovolume and giant magnetoresistance effects in doped $\text{La}_{2/3}\text{Ca}_{1/3}\text{MnO}_3$ perovskites

J. M. De Teresa, J. Blasco, M. R. Ibarra, J. García, C. Marquina, P. Algarabel, and A. del Moral

Departamento de Física de la Materia Condensada e Instituto de Ciencia de Materiales de Aragón, Universidad de Zaragoza-CSIC, 50009-Zaragoza, Spain

$\text{La}_{0.62}\text{Tb}_{0.05}\text{Ca}_{0.33}\text{MnO}_3$ and $\text{La}_{0.6}\text{Y}_{0.07}\text{Ca}_{0.33}\text{MnO}_3$ have been studied in order to probe into the mechanisms responsible for the giant magnetoresistance ratios observed in this kind of compound. The experiments have shown a strong connection between the magnetotransport and magnetovolume properties. A large volume effect appears above T_c which collapses with applied magnetic field or when the long range magnetic order sets in. Above T_c the magnetostriction and magnetoresistance isotherms are highly correlated. Charge localization with local distortion appears to be responsible for the transport and volume properties at zero field. Charge mobility and a more normal volume dependence on temperature are restored by applying high enough magnetic fields.

I. INTRODUCTION

A lot of experimental and theoretical effort is currently being devoted to understand the intriguing behavior of $\text{R}_x\text{B}_{1-x}\text{MnO}_3$ ($\text{R}=\text{rare earth}$, $\text{B}=\text{Ca, Sr, Ba, Pb}$) and related compounds.¹⁻¹⁰ The main interest of some of these compounds is the exhibition of giant magnetoresistance (GMR) ratios across a wide range of temperatures. The understanding of the relevant mechanisms which produce the GMR in these perovskitelike materials is of great importance due to the vast technological applications of GMR devices.

Recent works on $\text{Pr}_{1/2}\text{Sr}_{1/2}\text{MnO}_3$ (Refs. 5 and 11) have given evidence for charge ordering accompanied by a first-order change of the lattice parameters which strongly increases the resistivity. In this article we study the volume change of doped $\text{La}_{2/3}\text{Ca}_{1/3}\text{MnO}_3$ across the temperature range where GMR ratios are observed. In these compounds the resistance shows a maximum at around T_c , when the ferromagnetic long-range order sets in, marking the crossover from a nonmetallic state to a metallic one. The highest GMR ratios appear around T_c . The presence of lattice distortions above T_c was assumed to be a signal of charge localization.¹² Consequently resistance and volume effects would be highly correlated in this region. Simultaneous measurements of resistance and linear thermal expansion have been carried out to check this possibility. The effect of applying a magnetic field on the transport and volume properties has also been measured through magnetoresistance (MR) and magnetostriction (MS) experiments up to 12 T. The collapse of the charge-ordering state under applied magnetic field in $\text{Pr}_{1/2}\text{Sr}_{1/2}\text{MnO}_3$ has recently been reported⁵ and consequently the GMR ratios in doped $\text{La}_{2/3}\text{Ca}_{1/3}\text{MnO}_3$ can be connected with the collapse of the localized-charge state under applied magnetic field.

II. EXPERIMENT

The samples were prepared using a gel precursor in order to obtain well-mixed reagents. Stoichiometric amounts of La_2O_3 , Tb_4O_7 (Y_2O_3 in the yttrium-doped compound), CaCO_3 , and MnCO_3 with nominal purities >99.9%, were

dissolved in concentrated nitric acid resulting in a light solution. Afterwards, citric acid and ethylene glycol were added in a ratio of 4 g citric acid to 1 ml ethylene glycol and 1 g metal nitrates. The solution was heated and the excess nitric acid and water were boiled off giving a brown (yellow-brown in the yttrium-doped compound) gel. The gel was heated to give a black-brown (brown in the yttrium-doped compound) powder. This precursor was calcined at 1173 K overnight. The remaining black powder was cold pressed to 4 kbar and sintered at 1273 K for 3 h with intermediate grindings. Finally the pellet was sintered at 1573 K for 8 h resulting in a hard black ceramic material. The samples were analyzed by means of x-ray powder diffraction resulting in a single phase with a perovskitelike structure.

A superconducting coil was used to produce steady magnetic fields up to 12 T. Both resistance (MR) and thermal expansion (MS) were simultaneously measured in two different pieces of the same sample in order to correlate both properties. Resistance (MR) was measured with the standard four points technique; the contacts were done with silver paste on bar-shaped samples. The magnetic field was applied parallel to the current. Linear thermal expansion ($\Delta L/L$) was measured using the strain-gauge technique. The volume thermal expansion ($\Delta V/V$) was calculated as three times the linear thermal expansion. For the MS results the strain parallel (λ_{\parallel}) and perpendicular (λ_{\perp}) to the applied field was measured. Volume magnetostriction (VMS) and anisotropic magnetostriction (AMS) are straightforwardly calculated as $\omega = \lambda_{\parallel} + 2\lambda_{\perp}$ and $\lambda_r = \lambda_{\parallel} - \lambda_{\perp}$, respectively.

Magnetization and initial magnetic susceptibility (χ_{ac}) under applied fields up to 5 T were carried out with a quantum interference device magnetometer (SQUID).

III. RESULTS AND DISCUSSION

Magnetization measurements (not presented here) gave ferromagnetic order at $T_c \approx 220$ K for the terbium-doped compound and $T_c \approx 160$ K for the yttrium-doped compound. These temperatures coincide with the maxima of the resistance at zero field shown in Fig. 1. Consequently the onset of ferromagnetism makes the samples leave the nonmetallic

FIG. 1. Resistance vs temperature at 0, 1, and 12 T and MR(%) at 12 T of (a) $\text{La}_{0.62}\text{Tb}_{0.05}\text{Ca}_{0.33}\text{MnO}_3$ and (b) $\text{La}_{0.6}\text{Y}_{0.07}\text{Ca}_{0.33}\text{MnO}_3$.

state and enter the metalliclike state. This transition has recently been considered to be a first-order insulator-metal transition.⁹ It has been proposed⁹ that an abrupt increase in b (the matrix element which describes the electron hopping ratio between Mn sites) at T_c is a possible mechanism for the crossover from one state to the other.

The effect of applying a magnetic field is twofold (see Fig. 1). First the transition is shifted to higher temperatures and second the resistance values are strongly diminished in all temperatures. It brings about large MR values at 12 T ($\text{MR}(\%) = 100[\rho(0) - \rho(H)/\rho(H)]$) which are shown in Fig. 1. At around T_c , MR(%) reaches values of ≈ 700 for the terbium-doped compound and ≈ 3800 for the yttrium-doped compound. A strong connection between T_c values and MR ratios has been observed in other work:^{4,9,10} for lower T_c values, larger MR ratios are obtained.

The connection between resistance and volume effects is of great interest because it can give a new insight into the problem. In Fig. 2 we show the volume thermal expansion versus temperature under different magnetic fields. The insets show the differences obtained between the curves under zero and applied magnetic field. The volume thermal expansion curve under 12 T (this field has almost suppressed the nonmetallic state) is similar to the usual anharmonic lattice contribution. Under zero field (simultaneously with the strong resistance effect) an extra contribution appears. At $\sim T_c$ a strong lattice contraction ($\approx 0.8\%$) accompanies the crossover from the nonmetallic to the metallic behavior. This rather steep change of the lattice parameters at T_c can be

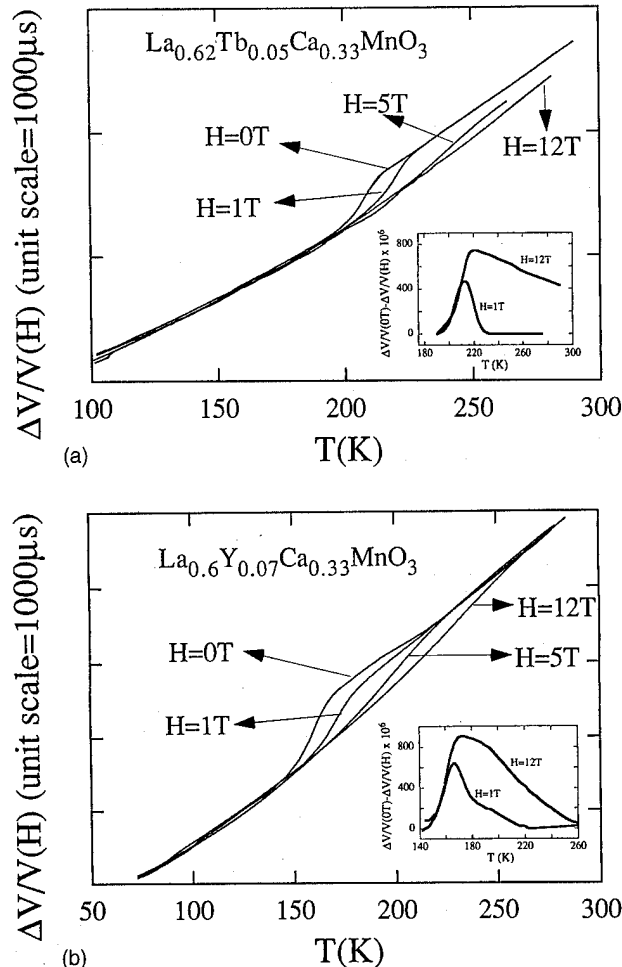

FIG. 2. Volume thermal expansion vs temperature at 0, 1, 5, and 12 T of (a) $\text{La}_{0.62}\text{Tb}_{0.05}\text{Ca}_{0.33}\text{MnO}_3$ and (b) $\text{La}_{0.6}\text{Y}_{0.07}\text{Ca}_{0.33}\text{MnO}_3$. The insets show the difference of the relative volume $\Delta V/V(0\text{ T}) - \Delta V/V(1\text{ T})$ and $\Delta V/V(0\text{ T}) - \Delta V/V(12\text{ T})$ obtained from these measurements.

related to the abrupt change of b claimed by Hwang *et al.*⁹ The extra contribution to the volume thermal expansion above T_c can be due to the progressive charge localization with decreasing temperature of the e_g Mn electrons¹³ until T_c is reached. This localization can cause a local distortion of the lattice. At T_c the insulator-metal transition accompanied by volume change would delocalize the e_g electrons and the metallic behavior would take place.

In Fig. 3 we show the isotherms of MR and VMS at different temperatures for the Tb-doped compound. Although GMR exists below and above T_c , the resistance isotherms have different shape in both regions. Below T_c [see inset of Fig. 3(a)] the curvature is always positive and a rapid change of resistance takes place at low fields. Above T_c the curvature changes from negative to positive at a field (H_c) which moves upwards with increasing temperatures. Below H_c the resistance is rather flat, evolving rapidly above H_c towards a tendency to saturation. The VMS (ω) and AMS (λ_r) versus temperature at the maximum field (12 T) are shown in Fig. 4. The AMS is the typical of a ferromagnet: zero above T_c and small below T_c . The VMS is intriguing: zero below T_c and very large above T_c . This unusual volume effect has its

FIG. 3. (a) Resistance vs applied magnetic field at temperatures $>T_c$. The inset shows the results at temperatures below T_c . (b) Volume MS as a function of applied magnetic field at temperatures above T_c .

maximum value at T_c and rapidly vanishes when the insulator-metal transition takes place. In Fig. 3(b) the shape of the VMS isotherms above T_c can be seen. The VMS isotherms are extremely similar to the MR isotherms. It seems evident that above T_c the transport and volume properties are intimately related with each other. It appears that both, the charge localization and the local distortion which take place at zero field, are released by applying a magnetic field, causing large MR and VMS effects. These effects are also visible

FIG. 4. Volume (ω) and anisotropic (λ_t) MS at 12 T vs temperature.

in the pure $\text{La}_{2/3}\text{Ca}_{1/3}\text{MnO}_3$ compound and will be published elsewhere.

In summary, MR and MS measurements have revealed a tight relationship between the transport and volume properties of doped $\text{La}_{2/3}\text{Ca}_{1/3}\text{MnO}_3$ above T_c suggesting a charge localization which causes a volume effect. These phenomena disappear at T_c , when the long range magnetic order sets in, where a large volume contraction takes place (0.8%), or by applying high enough magnetic fields, bringing about GMR ratios and large VMS values above T_c .

The substitution of La^{+3} by smaller Y^{+3} ions in mixed valence $\text{Mn}^{+3}\text{--Mn}^{+4}$ perovskites $\text{La}_{0.67-x}\text{Y}_x\text{Ca}_{0.33}\text{MnO}_3$ gives rise to a decrease of the order temperature ($T_c=160\pm5$ K for $x=0.07$ and $T_c=240$ K for $x=0$). One of the most relevant features found in this compound was the extremely large magnetoresistance observed in bulk polycrystals ($\approx -10\,000\%$) near T_c .¹ This huge effect was associated with the reduction of the lattice parameter. In order to have an insight into the influence of volume change on transport properties in this compound, we have performed measurement of the thermal dependence of the resistivity under hydrostatic pressure up to 8 kbar. At ambient pressure a peaklike anomaly in the resistivity is observed at T_c . Under the former assumptions, one would expect an increase of the resistivity value at the maximum as well as a decrease of T_c . However, we have found a shift toward higher temperatures and a drastic decreasing of the maximum in the resistivity for increasing pressures. At a pressure of 7.5 kbar the anomaly in the resistivity almost disappears and consequently the GMR effect. As a consequence, the effect of pressure seems to be identical to the effect of the applied magnetic field. Ibarra *et al.*² recently observed a large spontaneous magnetovolume effect at T_c with an extra contribution to the lattice thermal expansion. This extra contribution was found to be suppressed by an applied magnetic field. From these preliminary results it seems that the interplay between magnetostrictive deformations and the shrinkage of the lattice by external pressure could be in the origin of the observed behavior.

Hall effect and giant magnetoresistance in lanthanum manganite thin films

J. E. Núñez-Regueiro,^{a)} D. Gupta, and A. M. Kadin

Department of Electrical Engineering, University of Rochester, Rochester, New York 14627

Magnetoresistance and Hall coefficient have been investigated as a function of temperature in patterned thin films of La-Ca-Mn-O. Our data on magnetoresistance show a maximum magnetoresistance ratio $\Delta\rho/\rho(0)$ of $\approx -60\%$ at 1.5 T and 240 K. The Hall coefficient indicates that the carriers are predominantly holes, with apparent density that varies as a function of temperature. Although changes in mobility were also observed, our results indicate that changes in carrier density become more important than changes in mobility at temperatures lower than the Curie temperature. We interpret our data in terms of a simple picture that includes two parallel contributions to the carrier density and the conductivity. © 1996 American Institute of Physics.

[S0021-8979(96)52308-7]

The correlation between electric and magnetic properties of manganese oxides has drawn a good amount of attention for more than 40 years.¹⁻⁴ Lanthanum manganite, LaMnO_3 , has a perovskite crystalline structure and exhibits a range of magnetic phases when divalent atoms (Ca, Ba) are substituted on the La site. As the temperature is lowered, most manganites exhibit a nonzero spontaneous magnetization at a temperature T_c , indicating that some sort of ferromagnetic coupling is present. Interest in these mixed valence compounds has been revived recently in connection with giant negative magnetoresistance in ferromagnetic thin films⁵⁻¹² with compositions such as $\text{La}_{0.67}\text{Ca}_{0.33}\text{MnO}_3$ (LCMO). Upon application of a large magnetic field, the electrical resistance of such films can drop by a factor of more than 1000, at a temperature somewhat below the ferromagnetic transition.⁵ The origin of this effect is not well understood, although qualitative explanations involving magnetic polaron scattering, double exchange, and metal-insulator transitions have been discussed.^{1,6}

A necessary condition for the electric conduction is the presence of mobile carriers. As was shown by Jonker and van Santen,² this is satisfied when the Mn ions are in a mixed $+3/+4$ valence. They showed that in the case of LaMnO_3 , substitution of x atoms of trivalent La by divalent Ca forces x Mn atoms to become tetravalent. In the ideal case, each Mn^{+4} ion contributes one hole to the total number of carriers. However, doping is not the only mechanism by which carriers are induced. The fact that these compounds behave like antiferromagnetic semiconductors at both ends of the composition diagram (LaMnO_3 - CaMnO_3) (Ref. 2) is a good indication that thermal ionization of some Mn^{3+} ions is also possible. Based on the assumption that the carrier density would yield information about the nature of the transition in perovskite-type manganites, we investigated the Hall coefficient as a function of temperature in patterned thin films of LCMO. Our results indicate that changes in carrier density become more important than changes in mobility at temperatures lower than the Curie temperature.

Our 6000 Å films were deposited by rf sputtering from a powdered target with composition $\text{La}_{2/3}\text{Ca}_{1/3}\text{MnO}_3$ onto LaAlO_3 (100) substrates, using a process¹³ that had been

optimized for the high- T_c perovskite superconductor $\text{YBa}_2\text{Cu}_3\text{O}_7$ (YBCO). Sputtering gases were Ar and O_2 , with partial pressures of 10 and 5 mTorr, respectively. The substrates were held at 630 °C during deposition, and cooled down in 100 Torr O_2 . X-ray diffraction analysis at room temperature indicates that as-deposited films grew epitaxially on the LaAlO_3 substrate with a perovskite-type cubic structure, with lattice parameter $a=3.84$ Å.

The inset in Fig. 1 shows the pattern used for measuring both the Hall voltage and the longitudinal resistance. The bias current terminals are labeled $I+$, $I-$, the longitudinal voltage was read between V_{1+} and V_{1-} ($V_L = V_{1+} - V_{1-}$), and the transverse voltage was taken between V_{t+} and V_{t-} ($V_t = V_{t+} - V_{t-}$). The distance w between transverse voltage electrodes was 4.2 mm. This pattern was photolithographically defined and etched with a 50 H_2O_2 : 1 H_2SO_4 : 1000 H_2O solution. The resistivity of patterned samples seemed to be unaffected by the etching process, as compared to their unpatterned counterparts. Indium contacts were soldered onto the film. Samples were mounted in a temperature controlled cryostat cooled by liquid N_2 flow, surrounded by a superconducting solenoid capable of generating homogeneous magnetic fields of up to 4 T. Both longitudinal resis-

FIG. 1. Transverse voltage vs T for the positive [$V_t(B)$] and negative [$V_t(-B)$] sense of magnetic field. $B=1.5$ T. The inset shows the pattern used for Hall effect measurements. A magnetic field pointing into the page is defined positive.

^{a)}Electronic mail: nunez@ee.rochester.edu

FIG. 2. ρ vs T for an LCMO thin film, for $B=0$ and 1.5 T. The solid lines are fits to Eq. (1), for parameters $\alpha=223$ S/cm, $\beta=243$ S/cm, $T_c=232$ K, $E_0/k=790$ K, and $M_s=350$ emu/cm³, as discussed in Ref. 7.

tance and transverse voltage were measured under constant current bias ($I_L=1$ mA) as a function of temperature and applied magnetic field. The direction of the field was normal to the substrate, therefore at right angles with the current. The sense of the field was reversed in different runs. In order to avoid errors arising from longitudinal heat flow, the sample was thermally sunk to a temperature controlled copper block, and the current leads were wound around thermal binding posts. All measurements were repeated under slow cool-down and slow warm-up, yielding the same results. These results were also reproduced in subsequent runs for different values of magnitude and sense of I_L .

Samples studied show a sharp peak in the longitudinal resistivity which indicates a transition from a thermally activated semiconducting-like region ($d\rho_L/dT < 0$) to a metallic-like region ($d\rho_L/dT > 0$). Both the abscissa and ordinate of the peak in the ρ_L vs T curve are strongly affected by externally applied magnetic fields. As the field is increased the amplitude of the peak is reduced and the maximum shifts to higher temperatures. Figure 2 shows a plot of ρ_L vs T of a typical sample with and without an applied field of 1.5 T. The symbols are the experimental data, the solid lines are their corresponding fit to the phenomenological expression:⁷

$$\rho_L = 1/\sigma_L = 1/\{\alpha[M/M_s]^2 + \beta \exp(-E_0/kT)\}, \quad (1)$$

where σ_L is the longitudinal conductivity, M represents the microscopic magnetization of spins within a magnetic domain, M_s is the saturation magnetization ($M_s=350$ emu/cm³),⁷ and α and β are constants. $M=M(B,T)$ was determined from the mean-field expression¹⁴ for an average spin of 1.83 for the Mn ions. In fitting Eq. (1) to the data of Fig. 2, the values of α and M_s are fit to the low temperature data; those for β and E_0 are determined by fitting to the high-temperature data. The only other parameter is T_c , which is close to the temperature of the maximum resistance for $B=0$. In this way, we obtained the curves also shown in Fig. 2, using $\alpha=223$ S/cm, $\beta=243$ S/cm, $T_c=232$, and $E_0/k=790$ K. Here, T_c represents the effective magnetic transition temperature of a large portion of the material, even if some portions have higher transitions. Equation (1) pre-

dicts a giant magnetoresistance (MR), defined here as $MR=[\rho_L(1.5\text{ T})-\rho_L(0)]/\rho_L(0)$, at just below T_c . In our case, MR was $\sim -60\%$ at 240 K. Equation (1) was found to fit data from other thin films and single crystals, with similar values of the fitting parameters.⁷ In particular, we could account for the "colossal" MR observed in some samples¹² merely by lowering the value of T_c to 90 K.

Although the fit of Eq. (1) is very good in the large field, the zero-field peak is lower and more rounded in the experiments than in the model. We believe this is a consequence of an inhomogeneous distribution of Curie temperatures, which is suggested by a broadened magnetization curve near T_c in preliminary data on this sample,⁷ comparable to that in other similar thin films. This would tend to show up more strongly in the zero-field resistance than that at higher fields, or in the magnetization itself. That is because the resistance should change sharply below T_c , and the current will tend to follow the path of least resistance. Hence even a relatively small percentage of a higher- T_c material could have a disproportionate effect on $\rho_L(T)$. In larger fields, since $M(T)$ does not change as sharply, the variation in ρ among inhomogeneous regions should be reduced, and hence the deviation from homogeneous behavior should be much less.

The MR has sometimes been attributed to changes in scattering rates, but the "colossal" changes in the manganites seem to be more suggestive of a metal-nonmetal transition where the carrier density changes. For conduction by carriers of a single type and sign, the conductivity can be expressed within a Fermi liquid picture as a product of the carrier density p and the mobility μ : $\sigma_L = p e \mu$, where we are anticipating that the carriers will be holes with charge $+e$. One can then determine the carrier density from the transverse Hall field $E_H = -\mathbf{v} \times \mathbf{B} = (-1/pq) \mathbf{J} \times \mathbf{B}$. In a Cartesian coordinate system, where I_L , V_t , and B are, respectively, parallel to the x , y , and z -directions, $p = J_x B_z / e E_H$, where J_x is the current density.

It is worth noting that the extraction of information from Hall effect measurements in materials showing appreciable magnetization is not straightforward.¹⁵ A complete analysis of the Hall effect in magnetic materials normally requires measurement up to large magnetic fields to separate the "anomalous" Hall effect (associated with skew scattering) from the "ordinary" Hall effect associated with the carrier density). In the present case, however, going up to very large fields would be expected to change the effective carrier density, the very parameter that we want to measure. To avoid such confusion in these preliminary measurements, we have taken a deliberately naive approach, and treated the entire Hall voltage (at the moderate field of 1.5 T) as arising from the ordinary Hall effect. This should be reasonably accurate for $T > T_c$, but would be much less so for $T \ll T_c$, when M becomes fairly large. With this proviso, we continue with our analysis.

We used the Hall effect in order to attempt to separate out the effects of both carrier density and mobility. In this experiment, it is important to note that the measured trans-

FIG. 3. Temperature dependence of hole density (p) and mobility (μ) for an LCMO thin film in a field of 1.5 T.

verse voltage does not consist simply of the Hall voltage (as it would in the ideal situation), but rather is dominated by a superimposed component of the longitudinal voltage, as is illustrated in Fig. 2. We separate these two parts by their response to a change in the sign of B : a magnetoresistive component should be unchanged if B is reversed, while the Hall voltage should be reversed. Thus, we determine the true Hall voltage as the odd part of the measured transverse voltage, or the Hall field as $E_H = [V_t(B) - V_t(-B)]/2w$. If the difference becomes very small (as it does below 160 K), then the determination of the Hall field becomes uncertain. In our case, E_H was measured at 1.5 T, using the configuration shown in Fig. 1. The possibility that E_H arose from variations in the applied magnetic field in different runs, or from other artifacts, was ruled out since the observed longitudinal voltage did not show significant changes [$V_L(B) \approx V_L(-B)$].

Once p is known, μ can then be estimated from $\mu = 1/\rho_L e p$, where ρ_L is the measured longitudinal resistivity. Figure 3 is a plot of the effective carrier density and the effective mobility versus temperature of a typical sample. Our results show that majority carriers are of positive sign. As the temperature is reduced, the apparent carrier density decreases, then turns around and increases again sharply. Since the unit cell volume is $\sim 5.7 \times 10^{-23} \text{ cm}^3$, the carrier density falls from 0.07 carriers/unit-cell at room temperature to 0.02 holes/unit cell at the resistance peak (T_{peak}), levels off and starts rising again at T_c , approaching 0.06 holes/cell at 165 K. Below T_c the carrier density is expected to grow as the number of ferromagnetic ions increases. Based on stoichiometry, the estimated carrier density of a $\text{La}_{2/3}\text{Ca}_{1/3}\text{MnO}_3$ sample may be expected to approach 0.33 holes/cell as the temperature approaches $T=0$. Changes in mobility were also observed, but they appear to become significant in the region $T_c < T < T_{\text{peak}}$, where the carrier density shows little variation. This temperature range coincides with the region in temperature where the strongest MR changes are usually reported.^{9,12} When $T > T_{\text{peak}}$, changes in both carrier density and mobility seem to affect the conductivity.

The data for carrier density and mobility can be qualitatively understood in the following manner: In the high tem-

perature semiconducting state, as the temperature is cooled, the carriers freeze out, and in addition the mobility increases somewhat (due in part to decreased scattering from carriers). In the low temperature metallic phase, the mobility increases a bit more and then saturates, due perhaps to decreased spin-flip scattering as the material orders magnetically. However, since this correlates with the strength of the magnetization in the ferromagnetic state, the carrier density reverses direction in the metallic phase, and continues to increase as the temperature is cooled further.

We have investigated magnetoresistance and Hall coefficient as a function of temperature in patterned thin films of La-Ca-Mn-O . We found that our data can be interpreted in terms of a simple picture that includes two parallel contributions to the carrier density. This picture is also consistent with most of the experimental results reported to date on giant negative magnetoresistance in both thin films and single crystals of perovskite type manganites.

The Hall coefficient indicates that the carriers are predominantly holes, with apparent density that varies as a function of temperature. Although changes in mobility were also observed, our results indicate that changes in carrier density become more important than changes in mobility for $T < T_c$. It appears that the carrier density might be expressed as the sum of two terms as in Eq. (1), and the mobility is another factor that multiplies this to obtain the conductivity. A more quantitative description will require a more complete set of measurements, including determination of the anomalous Hall effect that may be associated with skew scattering. Future work will analyze p and μ for a range of applied fields as well as temperatures, and will attempt to incorporate both of these phenomena into a more complete phenomenological equation.

The effects of isovalent substitution into the lanthanide sites in $\text{La}_{1-x}\text{Y}_x\text{Ca}_{0.30}\text{MnO}_{3-\delta}$ oxides is presented. We report on the electrical and magnetic properties of these materials for $x=0-0.25$. We have found that the ferromagnetic ordering temperature *decreases* and the cusp of the resistivity occurring at this temperature *increases* when the smaller lanthanide Y is introduced into the lattice. We will provide evidence that a key signature of the magnetic properties of these oxides is the presence of an unusual long tail in the magnetization versus temperature curves $M(T)$, extending up to $3T_M$ and which is very sensitive to the applied magnetic field and becomes increasingly important with the concentration of Y in the lattice. These features signal a strong polarizability of the spin clouds in these materials as our Mössbauer experiments will clearly demonstrate. Finally, we will show that the magnetoresistance of these compounds can be well-described in terms of a spin-disorder scattering mechanism. © 1996 American Institute of Physics.

I. INTRODUCTION

The dynamics of charges in systems having strong electron correlations and near the Mott transition have received a renewed interest since the discovery of high-temperature superconductivity in the cuprate oxides. One of the most remarkable features of these systems is that a strong spin-charge coupling can exist and the dynamics of carriers is expected to be strongly dependent on the spin arrangement. The recent discovery of dramatic magnetoresistive effects in manganese perovskites is a very spectacular example of this strong interplay between itinerant carriers and localized magnetic moments.¹⁻³

It was known long ago that LaMnO_3 and CaMnO_3 are antiferromagnetic (AF) insulators;^{1,4} however, when a solid solution $\text{La}_{1-x}\text{Ca}_x\text{MnO}_3$ is formed, the existence of both $\text{Mn}^{3+/4+}$ ions has profound effects on the crystal structure, the spin arrangement and the transport properties. For $x \approx 0.2-0.4$ the compounds are metallic and ferromagnetic. It is close to the transition from the paramagnetic state to the ferromagnetic state where a cusp in the resistivity has been observed. Application of an external magnetic field of a few teslas suppresses the resistive cusp. Magnetoresistivity values as high as a 10⁶% have been reported.³

Although a detailed microscopic understanding of such huge magnetoresistive effect is not yet available, the simple observation of the fact that a high field is required to suppress a scattering channel immediately suggests that we are dealing with the internal, atomicleike exchange fields of these materials. This is just the opposite behavior as observed in metal-based giant-magnetoresistive materials which require fields of only a few Oe to show the maximal change of resistivity (although much smaller $\approx 100\%$!!⁵). The appearance of a metallic ferromagnetic state on doping has been explained by the mechanism of the double exchange.⁶ Due to the Hund rule, the Mn^{3+} ions in LaMnO_3 have three electrons in the t_{2g} orbitals and a single electron in the e_g orbital. Because the Hund rule and the on-site Coulomb repulsion between e_g electrons, LaMnO_3 is an AF insulator. The sub-

stitution of La atoms by divalent ions (Ca^{2+} , Sr^{2+} , Ba^{2+}) leads to a depletion of the e_g orbitals which now become available for electrons of the surrounding Mn^{3+} ions to jump into the empty states as long as the hopping electron has its spin parallel to the t_{2g} spins. This means that the magnetic moments of the Mn^{3+} and Mn^{4+} should be parallel for metallic conduction. The AF coupling between the $\text{Mn}^{3+/4+}$ ions should be overcome by the gain of kinetic energy of the itinerant electrons in order to stabilize a metallic and ferromagnetic state.⁶ It is clear that AF is controlled by the hopping integral t_{ij} between ionic sites which thus should be strongly dependent on the overlapping of the 3d orbitals. Therefore, one can expect that distortion of the Mn-O-Mn bond should result in a severe change of the coupling between itinerant carriers and localized spins.⁷

In this letter, we will explore some effects of introduction of a smaller trivalent lanthanide (Y^{3+}) in the La sites.

II. EXPERIMENT

Ceramic samples of $\text{La}_{0.7-x}\text{Y}_x\text{Ca}_{0.3}\text{MnO}_3$ ($x=0-0.25$) composition were prepared by solid state reaction of precursor oxides. Appropriate amounts of La_2O_3 , CaO , Mn_2O_3 and Y_2O_3 were mixed and heated in air at 900 °C for 24 h with intermediate grinding. A final sintering process step was carried out at 1400 °C. The as-prepared materials were characterized by x-ray diffraction. They are single phase and have an orthorhombic perovskite structure (Pbnm). The lattice parameters are found to vary linearly with the Y concentration.⁷ Plasma, chemical, and ATD analysis have been used to check the sample composition and stoichiometry. Within the context of this letter the relevant results of such analysis are that the oxygen contents of the samples does not vary significantly with the Y composition and the measured ratio Y/La follows the expected changes.⁸ Magnetoresistivity measurements have been performed under fields up to 5.5 T by conventional four-probes method with the current parallel to the applied field. Magnetic properties have been measured by

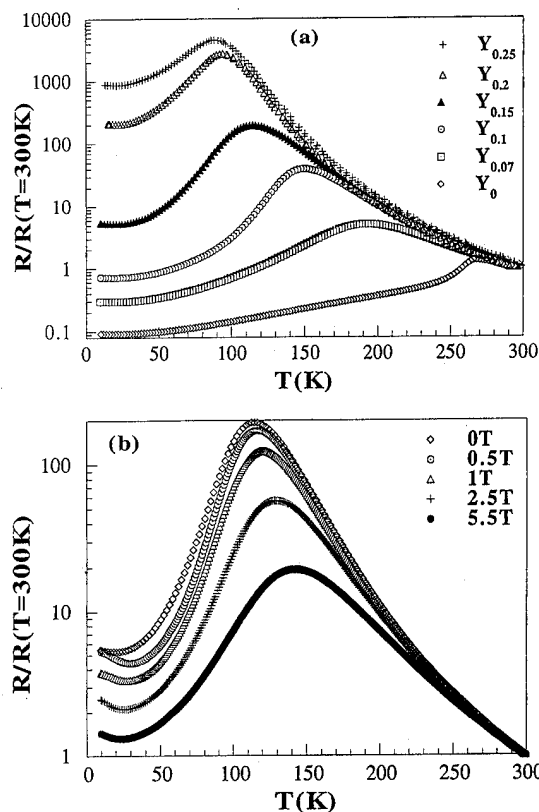

FIG. 1. (a) Normalized resistivity vs temperature for $\text{La}_{1-x}\text{Y}_x\text{Ca}_{0.33}\text{MnO}_{3-\delta}$ ($x=0-0.25$). (b) Normalized resistivity vs temperature for $x=0.15$ at several applied magnetic fields.

using a QD SQUID magnetometer up to 5.5 T. Mössbauer experiments were performed on ^{57}Fe doped samples (2%) by using a $^{57}\text{CoRh}$ source. Spectra were recorded at several temperatures. When necessary a magnetic field of 0.3 T was applied to the sample and perpendicular to the γ -ray beam.

III. RESULTS AND DISCUSSION

Figure 1(a) shows the zero-field temperature dependence of the resistivity of some of the samples. A giant resistive peak develops at low temperature. Its amplitude $\Delta R(T)/R = [R_{\text{max}} - R(300 \text{ K})]/R(300 \text{ K})$ is as high as 5×10^5 for $L = \text{Y}_{0.25}$. At temperatures well below the resistivity peak, a metalliclike behavior is almost recovered. The most remarkable results of Fig. 1(a) are the lowering of the temperature T_M where the maximum resistance (R_{max}) occurs when increasing the Y concentration, and the systematic enhancement of R_{max} . The application of a magnetic field strongly reduces the resistivity as shown in Fig. 1(b). The magnetoresistance $\Delta R(H)/R = [R_{\text{max}}(H) - R(5 \text{ K}, 5 \text{ T})]/R(5 \text{ K}, 5 \text{ T})$ reaches its maximum at temperatures close to T_M , decreasing above and below T_M .

From the structural point of view, the Y substitution is expected to enhance the buckling of the MnO_6 octahedra, thus leading to a reduction of the Mn-O-Mn bond. As a consequence, the transfer interaction of e_g electrons should be reduced. Therefore, our results indicate that a reduction of t_{ij} produces a lowering of T_M and an enhancement of the magnetoresistance.⁷

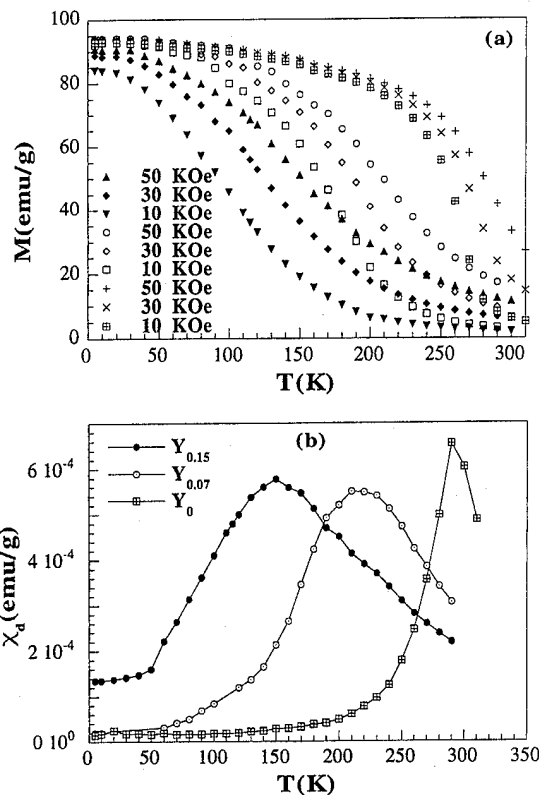

FIG. 2. (a) Temperature dependence of the magnetization of the $x=0, 0.07$, and 0.15 samples at several fields. (b) High-field differential susceptibility for the same samples as a function of temperature.

We turn now to the magnetic properties. In Fig. 2(a) we present some of the magnetization versus temperature curves measured at several fields. ($H=10, 30$, and 50 kOe) for samples having $x=0, 0.07$, and 0.15 . Several aspects of these data should be pointed out. First, the drop of magnetization at the ferromagnetic ordering temperature T_M closely coincides with the temperature where the cusp in the resistivity is observed. Both temperatures decrease with increasing the Y concentration into the lattice. At $T \ll T_M$ the saturated magnetization is of about $3.7 \mu_B$ in accordance with the classical value expected for e_g electrons ($0.7/f.u.$) fully polarized by the t_{2g} localized spins ($S=3/2$). The weak dependence of the 0 K magnetization on the Y concentration could reflect the existence of some noncollinear spin arrangement. Notice that at 5 T this difference is further reduced. It should also be noticed in Fig. 2(a) that at T_M , for the $x=0.15$ sample, a field of 5 T induces a magnetization which reaches about 75% of its saturated value at this temperature. Such an extraordinary magnetic polarizability is a key feature of these ferromagnetic manganites. Data of Fig. 2(a) displays a characteristic long tail extending up to the highest measured temperature (300 K) and which becomes more pronounced as the Y concentration increases. Comparison of the resistivity and magnetization curves reveals that it is along this long tail that resistivity rises when lowering temperature. As shown by data of Fig. 2(a), the magnetization in the tail is very sensitive to the applied magnetic field and so the magnetoresistivity is relevant in this temperature range. Figure 2(b), where we show the high field susceptibility of the samples as

FIG. 3. Temperature dependence of transmission Mössbauer spectra of ^{57}Fe : $\text{La}_{1-x}\text{Y}_x\text{Ca}_{0.33}\text{MnO}_{3-\delta}$ ($x=0.07$) sample. (a) 69 K, (b) 80 K (c) 90 K (d) 90 K and $H=3$ kOe, and (e) 100 K.

a function of temperature, clearly reflects the strong polarizability of the system, which is particularly relevant close to T_M .

Further evidence of the magnetic ordering and polarizability can be gained by using Mössbauer spectroscopy, which is a local probe of the magnetic ordering. In Fig. 3, we present the Mössbauer spectra recorded at various temperatures for the $x=0.07$ sample. From room temperature down to 100 K a singlet is observed: That means that in this temperature range the nuclear magnetic moment is rapidly precessing. At lower temperatures, as spontaneous magnetic order sets in, the magnetic moments become blocked and the typical 6-finger pattern of ^{57}Fe becomes apparent. At temperatures close to T_M (for instance 90 and 80 K in Fig. 3) the hyperfine splitting of the spectra gradually appears. In this letter we focus our attention to this temperature region. At $T < 90$ K the spectra can be fitted to a distribution (ΔH) of hyperfine fields which become progressively narrower when reducing temperature. At $T=90$ K, the distribution ΔH extends up to 500 kOe. At this point it should be mentioned that introduction of $\text{Fe}^{3+/4+}$ ions into the Mn sites, even at the low concentration used (2% ^{57}Fe) in principle can produce severe disturbances on the establishment of the ferromagnetic order and the metallic state. For instance the electronic $\text{Fe}:3d^{5/4}$ configuration can reduce electron jumping into this position thus resulting in a reduction of the kinetic energy and consequently the ferromagnetic state could be depressed. Our data of Fig. 3 seem to suggest that this is indeed the case as T_M is reduced from $T_M \approx 110$ K ($x=0.07$) to $T_M \approx 90$ K in the ^{57}Fe doped sample. In spite of this effect, the system still remains highly polarizable as will be seen in the following. We have recorded Mössbauer spectra under a magnetic field. In Fig. 3 we include the spectra collected at 90 K under an $H=3$ kOe field. Comparison of the spectra taken with and without field clearly reveals the more promi-

FIG. 4. Magnetoresistivity of the $x=0.07$ and $x=0.15$ samples as a function of the differential susceptibility at several temperatures.

nent development of the hyperfine sextet which reveals the strong field-induced polarizability. Notice that $H=3$ kOe is much smaller than the hyperfine field (up to 500 kOe).

The appearance of a giant resistive peak close to T_M suggests that spin-disorder scattering is a dominant scattering channel in these systems. Due to the fact that the resistivity at the cusp is much higher than the resistivity well above and below T_M , we can simply analyze the field dependence of the resistivity neglecting all other factors contributing to the overall resistivity and considering simply the spin-scattering term. The spin-disorder scattering term is expected to be a function of the differential susceptibility $\chi(T,H)$ and should increase with temperature. Therefore, we can write: $\rho(T,H) \propto F[T, \chi(T,H)]$ where F is some function. In Fig. 4, we plot the resistivity data for samples $x=0.07$ and 0.15 at temperatures close to the cusp of $\rho(T,H)$ as a function of $T \cdot \chi(T,H)$. It is very significant that data for samples having very distinct critical temperatures and values of the maximal resistivity (see Fig. 1) collapse onto a single function. This means that a common scattering mechanism is operating on all samples and the field dependence of the resistivity is simply given by a function of the susceptibility.

In summary we have shown that the giant magnetoresistivity response in these manganites is accompanied by an unusual magnetic polarizability of the electronic clouds. Both effects appear to be controlled by the mean size of the lanthanides, that is the concentration of the smaller Y ion into the lattice.

Results on structural and magnetic characterization of radio frequency sputtered thin films of $\text{La}_{0.74}\text{Pb}_{0.26}\text{MnO}_z$ on (100) Si are presented. Stoichiometric films with a thickness of $0.6\text{ }\mu\text{m}$ showing (110) textured growth were deposited in a mixed argon-oxygen atmosphere. The low temperature magnetization is 10% smaller than the expected value for a collinear ferromagnetic order in the oxide. Zero-field resistivity data show a metal-to-semiconductor transition centered at $T_{\text{ms}}=250\text{ K}$. Data on magnetoresistance ($\text{MR}=[\rho(0)-\rho(H)]/\rho(0)$) versus temperature reveal the following important features: (i) a maximum value of 22% for $H=2\text{ T}$ at the metal-to-insulator transition temperature, (ii) MR value of 15%–22% over the entire temperature range 4.2–300 K, and (iii) a substantial MR, $\sim 10\%$ even at temperatures as high as 380 K, well above the Curie temperature. Data on the temperature dependence of ferromagnetic resonance linewidth at 9.4 GHz show a discontinuity at T_{ms} . © 1996 American Institute of Physics. [S0021-8979(96)52408-3]

Jonker and co-workers,¹ about four decades ago, discovered ferromagnetism in a series of Mn and Co based perovskite compounds with the composition $\text{La}_{1-x}(\text{Ca,Ba,Sr})_x(\text{Mn,Co})\text{O}_3$. Zener attributed the ferromagnetic order to the double exchange (DE) interaction between Mn^{3+} and Mn^{4+} or Co^{3+} and Co^{4+} ions and the oxides are therefore known as DE ferromagnets.² Recent reports on the observation of a giant magnetoresistance (GMR) in the Mn-based perovskite oxides have generated a considerable interest in DE ferromagnets for useful technologies.^{3–5} A large MR, $\sim 60\%$ at room temperature, was observed in thin films of $\text{La}_{0.67}\text{Ba}_{0.33}\text{MnO}_z$.³ Thin films of La-Ca-Mn-O prepared by ion beam sputtering were found to show a maximum MR of 53%.⁴ A colossal MR, on the order of 127 000% in inflationary units, was reported for thin films of $\text{La}_{0.67}\text{Ca}_{0.33}\text{MnO}_z$.⁵ The very large MR, however, occurs at very high applied magnetic fields $H=5\text{--}8\text{ T}$, and is suggested to arise from a metal-to-semiconductor type transition, DE assisted processes and magnetic polaron scattering.^{3–5} Studies on single crystals of La-Sr-Mn-O reveal, in addition to GMR, a rich variety of phenomena including external field induced crystallographic transitions and giant magnetostriction.⁶

Here we report a similar GMR effect in thin films of $\text{La}_{1-x}\text{Pb}_x\text{MnO}_z$.⁷ Structural and magnetic properties of single crystals of the oxides with $x=0.25\text{--}0.45$ were reported in the late 1960s by Morrish and co-workers.^{8–11} The oxides order ferromagnetically with the Curie temperature T_C ranging from 315 to 350 K. Data on temperature dependence of the resistivity show a metallic to semiconductor transition at a certain temperature T_{ms} , and T_{ms} is dependent on x and is slightly smaller than T_C . The observation of a relatively large MR at ambient temperature, $\sim 20\%$ at T_{ms} for a field of 1 T could be of importance for potential device applications for the oxides.^{9,10} In this study films of $\text{La}_{0.74}\text{Pb}_{0.26}\text{MnO}_z$ with (110) orientation were deposited on (100) Si by rf sputtering in a mixed $\text{O}_2\text{--Ar}$ atmosphere, and were characterized by magnetization, ferromagnetic reso-

nance (FMR) and MR measurements. The low temperature magnetization for the film was $\sim 10\%$ smaller than the value expected for collinear ferromagnetic ordering of Mn moments. Data on FMR linewidth show a discontinuity at the metal-to-semiconductor transition at $T_{\text{ms}}=250\text{ K}$. A maximum $\text{MR}=[\rho(0)-\rho(H)]/\rho(0)$ of 22% was observed at T_{ms} for $H=2\text{ T}$. Details on these studies are provided in the following sections.

The technique of rf sputtering was used to prepare films of La-Pb-Mn-O. For film preparations a polycrystalline sintered target with the composition $\text{La}_{0.67}\text{Pb}_{0.33}\text{Mn}_{0.75}\text{O}_z$ prepared by standard ceramic techniques from powders of La_2O_3 , PbO , and MnCO_3 was mounted in a magnetron gun. The sputtering was carried out in a 20% oxygen and 80% argon atmosphere at a pressure of 40 mTorr and a rf power of 50 W at 13.6 MHz. Films were deposited on (100) Si substrates mounted on a heated platform placed at a distance of 6 cm below the target. Samples with thickness $0.6\text{ }\mu\text{m}$ were obtained for a sputtering duration of 24 h. The film composition determined by energy dispersive x-ray spectroscopy techniques was $\text{La}_{0.74}\text{Pb}_{0.26}\text{MnO}_z$.

As-deposited films were amorphous and annealing at $700\text{--}1000\text{ }^\circ\text{C}$ was necessary to crystallize the films. X-ray diffraction measurements performed on annealed films showed (110) orientation with a lattice constant $a=3.861\pm 0.004\text{ }\text{\AA}$ and a film-substrate lattice mismatch on the order of 0.5%.

Magnetization measurements were performed with a Faraday balance and a high field superconducting quantum interference device (SQUID) magnetometer. X-band ferromagnetic resonance data were obtained using a reflection type cavity. Magnetoresistance studies were carried out using the four-probe technique.

Films sputtered at a substrate temperature of $500\text{ }^\circ\text{C}$ were amorphous, paramagnetic at room temperature, and did not order magnetically down to 80 K. Magnetization (M) measurements showed evidence for a long range order in films annealed in air or oxygen at $T_a=600\text{--}1000\text{ }^\circ\text{C}$. In Fig.

FIG. 1. Magnetization as a function of temperature for a series of annealing temperatures for La-Pb-Mn-O films sputtered in a pure argon temperature.

1, M vs T data are shown for a static in-plane field of 5 kOe for a film sputtered in pure argon. The data indicate an increase in the low temperature M value with increase in T_a . However, M is found to decrease for $T_a = 1000^\circ\text{C}$, possibly due to the loss of Pb from the film. We also studied the effects of sputtering parameters such as the atmosphere and pressure on M . Both pure argon and oxygen-argon sputtered films showed same M value, but T_C for argon sputtered films were smaller than for films sputtered in oxygen-argon. An increase in the sputtering pressure, from 5 to 40 mTorr, resulted in an increase in M and T_C and could be due to changes in the film composition.

In this article, the focus is on magnetic properties of films sputtered in 20% oxygen-80% argon at 40 mTorr and annealed at 800°C in oxygen. Figure 2 shows the dependence of M on temperature. The measurements were done for an in-plane static field of 5 kOe. The Curie temperature obtained by linear extrapolation of high temperature M data is ~ 325 K and is in excellent agreement with the single crystal value of 319–328 K.⁹ One observes a long tail in the M vs T data close to T_C . The M value at 5 K is 73 emu/g and is 10% smaller than the value of 80.5 emu/g expected for a collinear ferromagnetic ordering of Mn moments and for Mn^{3+} and Mn^{4+} concentrations estimated from the compo-

FIG. 2. Magnetization measured with an in-plane static field of 5 kOe vs temperature data for a film of $\text{La}_{0.74}\text{Pb}_{0.26}\text{MnO}_2$ sputtered in mixed argon-oxygen atmospheres and annealed at 800°C in oxygen. The Curie temperature is 325 K.

FIG. 3. M vs H data for the film at 5 and 250 K. The field was applied parallel to the film plane.

sition. The discrepancy could be due to either a smaller than expected concentration of Mn^{3+} in the film or due to a canted ferromagnetic order. The presence of competing magnetic interactions in DE ferromagnets, i.e., positive double exchange and negative superexchange, could lead to canted ferromagnetism for certain compositions.¹² However, M data for single crystals provide no evidence for a canted spin structure.⁹ Thus it is quite likely that the film contains a larger than expected tetravalent Mn ions. Further studies are required for an understanding of the cause of reduction in M in the film. Figure 3 shows data on the static field dependence of M at 5 and 250 K the temperature at which resistivity ρ shows a maximum. In the ferromagnetic state, saturation of M occurs at $H = 100\text{--}500$ Oe. The coercive field increases with decreasing T . The data show a relatively small slope at fields above saturation as expected for ferromagnets.

FIG. 4. Temperature dependence of the ferromagnetic resonance linewidth at 9.3 GHz for the film. The static magnetic field was applied parallel to the film plane. The data show a discontinuity at the metal to semiconductor transition at $T_{ms} = 250$ K.

FIG. 5. Variation of resistivity ρ with the applied field H for a series of temperature.

Ferromagnetic resonance measurements were done at 9.3 GHz as a function temperature for H both parallel and perpendicular to the film plane. The g value at room temperature estimated from the resonance fields is 2.18. In single crystals, the g value remained constant at 1.97 and was independent of x in the paramagnetic state where, as in the ordered state it ranged from 2.07 (for $x=0.45$) to 2.15 (for $x=0.26$) and the strong dependence of g on x was suggested to arise from the formation of a spin polarized conduction band.¹⁰ The g value for the film is in very good agreement with the single crystal value of 2.15.¹⁰ Figure 4 shows the variation of FMR linewidth ΔH with T for the static field parallel to the film plane. A linear decrease in ΔH , from 1200 Oe at 100 K to 600 Oe at 250 K is observed when T is increased from 100 to 250 K. A temperature independent ΔH is measured for $T \geq 250$ K, a region in which the sample shows a semiconductorlike behavior. In single crystals ΔH dropped rapidly with T , showed a minimum at the metal-to-semiconductor transition temperature T_{ms} , and increased with further increase in T .¹⁰ The increase in ΔH below T_{ms} is attributed to an efficient spin-lattice relaxation process via the lattice orbitals of band electrons.¹⁰

The electrical resistivity ρ and its field dependence were measured using the four-probe configuration and a high field superconducting magnet. The static field was applied parallel to the film plane. For $H=0$, a metallic-type behavior with a maximum in ρ at 250 K was observed. With further increase in T , ρ decreased. Thus the transition from metallic to semiconductor type conduction occurs at $T_{ms}=250$ K, ~ 75 K below the Curie temperature. However, in single crystals T_{ms} is 30 K above T_C .¹⁰ In the presence of an external static field, ρ is found to decrease. Figure 5 shows ρ vs H data for a series of temperature. The largest decrease in ρ is observed at T_{ms} . The magnetoresistance $[\rho(0)-\rho(H)]/\rho(0)$ was determined for $H=0.5$ and 2 T and are plotted as a function of

FIG. 6. Magnetoresistance $[\rho(0)-\rho(H)]/\rho(0)$ vs temperature data for the film for applied fields of 0.5 and 2 T.

temperature in Fig. 6. For $H=0.5$ T, MR decreases linearly with T , from 15% at 5 K to 2% at T_C . When the field is increased to 2 T the data show a maximum value of 22% at the metal-to-semiconductor transition temperature. Magnetoresistance values of 15%–22% are observed over the entire temperature range 5–300 K. A substantial MR is observed for $T > T_C$, $\sim 10\%$ at 380 K. The observation of a large MR over a wide temperature interval could be of importance for useful applications. The MR values are in agreement with results for single crystals and textured (100) La–Pb–Mn–O films on single crystal LaAlO_3 substrates.^{10,13}

Composition dependence of giant magnetoresistance in $(\text{La}_{1-x}\text{Y}_x)_{2/3}\text{Ca}_{1/3}\text{MnO}_\delta$ ($0 \leq x \leq 1$)

Zisen Li, X. T. Zeng, and H. K. Wong^{a)}

Physics Department, The Chinese University of Hong Kong, Shatin, Hong Kong

We have prepared a series of polycrystalline bulk samples of $(\text{La}_{1-x}\text{Y}_x)_{2/3}\text{Ca}_{1/3}\text{MnO}_\delta$ ($0 \leq x \leq 1$), and studied their magnetization M , resistivity ρ , and low-field magnetoresistance (MR) in the temperature range $10 \leq T \leq 300$ K. The ferromagnetic transition temperature of the samples T_c decreases with increasing x . For each sample, both ρ and MR have peak values at a temperature close to T_c . The peak value of ρ increases rapidly with increasing x while the peak value of MR has a maximum at $x \sim 0.4$. We observed MR value [defined as $[\rho(0) - \rho(B)]/\rho(0)$] as high as 91% at $B = 0.85$ T. Some of the results could be explained by the semicovalent exchange theory of Goodenough [Prog. Solid State Chem. **5**, 145, (1971)]. © 1996 American Institute of Physics. [S0021-8979(96)52598-3]

I. INTRODUCTION

Nonparallel spin alignment is a prerequisite of the giant magnetoresistance (GMR) effects.¹ The dramatic change in resistivity in an external magnetic field is due to a spin-dependent scattering mechanism. In magnetic multilayers that exhibit GMR, there exists an antiferromagnetic (AFM) coupling between the otherwise ferromagnetic layers.¹ Similar AFM spin configuration can be found in many compounds that were previously studied in great depth. A typical example is the lanthanum manganites whose spin structures depend on the composition.² Chahara *et al.*³ noticed that in $\text{La}_{1-x}\text{Ca}_x\text{MnO}_3$ (LCMO), the Mn spins are coupled antiferromagnetically when $x < 0.2$.² They prepared LCMO thin films of this composition and observed a large MR $\approx 53\%$ for $B = 1$ T. Here we define $\text{MR} = [\rho(0) - \rho(B)]/\rho(0)$. At almost the same time, von Helmolt *et al.*⁴ observed $\text{GMR} \approx 60\%$ for $B = 7$ T in $\text{La}_{2/3}\text{Ba}_{1/3}\text{MnO}_3$ (LBMO) thin films and McCormack *et al.*⁵ obtained a colossal $\text{MR} \approx 99.9\%$ for $B = 6$ T in an epitaxial $\text{La}_{2/3}\text{Ca}_{1/3}\text{MnO}_3$ thin film. The last two compounds, $\text{La}_{2/3}\text{Ba}_{1/3}\text{MnO}_3$ and $\text{La}_{2/3}\text{Ca}_{1/3}\text{MnO}_3$, are purely ferromagnetic and the AFM coupling does not exist. Furthermore, special annealing treatments on these films must be done for the GMR effects to appear. It appears that high quality of crystallinity in the thin-film structures is tied to the GMR properties; however, manganite single crystals were available as early as in 1969: Leung, Morrish, and Searle grew $\text{La}_{1-x}\text{Pb}_x\text{MnO}_3$ single crystals and measured their electric and magnetic properties including the magnetoresistance; however, they did not observe a very large MR effect.⁶ This indicates that the crystal quality should not be a prerequisite for the GMR effect. In fact, Jin *et al.*⁷ reported recently that $\text{MR} \approx 99\%$ at $B = 6$ T can be obtained in sintered bulk samples of $\text{La}_{0.60}\text{Y}_{0.07}\text{Ca}_{0.33}\text{MnO}_\delta$ and attributed the improvement to a decrease of lattice constant. To gain further insight to this finding, we prepared a series of $(\text{La}_{1-x}\text{Y}_x)_{2/3}\text{Ca}_{1/3}\text{MnO}_\delta$ ($0 \leq x \leq 1$) (LYCMO), and studied their electric and magnetic properties. We found that these properties depend on x , the doping level of yttrium. A very

high GMR value (MR $\approx 91\%$) was observed in samples with $x \approx 0.4$ using only a low magnetic field ($B = 0.85$ T).

II. SAMPLE PREPARATION

Polycrystalline samples of $(\text{La}_{1-x}\text{Y}_x)_{2/3}\text{Ca}_{1/3}\text{MnO}_\delta$ with $x = 0\%$, 10%, 30%, 40%, 50%, 60%, and 100% were prepared by standard ceramic process. Stoichiometric amounts of La_2O_3 , Y_2O_3 , CaCO_3 , and MnO_2 were intimately mixed and ground in a small amount of alcohol for 48 h by a ball mill. The resultant slurry was dried and then pre-fired at 1000 °C for 8 h. The powder was ground again, pressed into small pellets, sintered at 1350 °C for 8 h in oxygen, and then cooled slowly to room temperature in air. All samples were made using identical procedures.

III. CHARACTERIZATION

Some of the samples were fractured and then investigated by a scanning electron microscope. Their grain morphology varied dramatically for different x . The grain sizes in most samples (including $x = 100\%$) were about 5 μm and the grains were well connected. The samples with $x = 40\%$ and $x = 50\%$ had elongated grains and were more porous than the other samples.

Their crystallographic structure was studied with an x-ray powder diffractometer at room temperature. It should be noted that the structures of the two end compounds $\text{La}_{2/3}\text{Ca}_{1/3}\text{MnO}_\delta$ (LCMO) and $\text{Y}_{2/3}\text{Ca}_{1/3}\text{MnO}_\delta$ (YCMO) were studied before. LCMO has a nearly cubic perovskite structure² while YCMO is orthorhombic.⁸ We reproduced these results and also found that for increasing x , the LYCMO structure varied gradually from a nearly cubic perovskite structure to an orthorhombic structure with decreasing lattice constants.

IV. MAGNETIC PROPERTIES

The magnetization of the samples were measured by an EG&G PAR vibrating sample magnetometer equipped with a 10 K closed-cycle refrigerator. Typical hysteresis loops at $T = 10$ K are shown in Fig. 1. For larger x , the saturation field is also higher and the saturation magnetization smaller. The temperature dependence of the magnetization M (magnetic

^{a)} Author to whom correspondence should be addressed.

FIG. 1. Hysteresis loops for LYCMO.

moment per unit mass) is shown in Fig. 2. Care should be exercised in determining the Curie temperature T_c of these polycrystalline ceramics. Since most samples do not have a sharp transition, the Arrott plot method or similar approach is not appropriate. We determined the Curie temperatures by an extrapolation procedure described by Leung and co-workers.⁶ The results obtained by this method match the metal-semiconductor transition temperatures as summarized in Table I.

V. RESISTIVITY AND MAGNETORESISTANCE

The bulk materials were sliced with a diamond saw into thin sheets of approximately 8.5 mm in length, 2 mm in

FIG. 2. Temperature dependence of magnetization.

TABLE I. Properties of $(\text{La}_{1-x}\text{Y}_x)_{2/3}\text{Ca}_{1/3}\text{MnO}_3$. MR_{max} : peak value of MR measured at $B=0.85$ T; ρ_{max} : peak value of resistivity; a : lattice constant. MR_{max} and ρ_{max} occur at temperatures T_1 and T_2 , respectively.

Composition x (%)	a (Å)	T_1 (K)	MR_{max} [$\Delta\rho/\rho(0)$] (%)	T_2 (K)	ρ_{max} (kΩ cm)
10	7.6936	161	64.3	181.2	9.40×10^{-4}
30	7.6870	65.8	79.2	70.8	13.0
40	7.6712	53.1	90.9	57.7	60.8
50	7.6610	39.7	73.6	35.0	12.5×10^4

width, and 0.7 mm in thickness for electrical transport measurements. The electrical resistance and magnetoresistance were measured by the four-point probe technique in a temperature range of $10 \text{ K} \leq T \leq 300 \text{ K}$ and magnetic field $B < 1$ T. In view of practical applications, such a low field range is of much importance. The contacts were made by depositing silver pads on the thin specimens. For samples with high resistivity, a Keithley 610 C electrometer had to be used. The resistivity for each sample as a function of temperature was measured using the same measurement current.

All samples except the ones with $x=100\%$ and $x=60\%$ showed a metal-semiconductor transition. At a fixed temperature, the resistivity increased rapidly with increasing doping level x as shown in Fig. 3. In contrast, the MR value has only a moderate x dependence. The highest value of MR was obtained for the sample with $x=40\%$ as shown in Fig. 4. At zero field, this sample has a sharp metal-semiconductor transition at $T \approx 57.7$ K. At $B=0.85$ T, the transition shifts to $T \approx 67$ K but with a broad cusp. The MR value peaks at $T=53$ K and has a remarkable value of about 91% for a low magnetic field $B=0.85$ T. In comparison, Jin *et al.* obtained 99% for $B=6$ T.⁷ The field dependence of the resistivity exhibits a hysteresis effect as illustrated in Fig. 5. Table I lists the major properties of our samples. It is interesting to note

FIG. 3. Composition dependence of resistivity at different temperatures.

FIG. 4. Temperature dependence of $\rho(0)$, $\rho(B)$, and MR for LYCMO ($x=40\%$); $B=0.85$ T.

that the samples with $x=40\%$ and $x=50\%$ show relatively strong MR effect but they are porous. The results may suggest that the grain boundaries play a major role in this property.

VI. DISCUSSION

Substitution of La by Y in LCMO must influence the lattice structure and their properties. Goodenough discussed

FIG. 5. Hysteresis of the resistivity $\rho(B)$ with applied magnetic field; $T=53$ K.

the large cation effect based on his semicovalent exchange theory.² Because Ca has a smaller ionic size than Sr and Ba, $\text{La}_{1-x}\text{Ca}_x\text{MnO}_3$ forms solid solutions of perovskite structure throughout the entire composition range: $0 \leq x \leq 1$.⁹ Since La, Ca, and Y occupy the same lattice sites and the Y^{3+} ionic size $\approx \text{Ca}^{2+}$ ionic size $< \text{La}^{3+}$ ionic size, we expect that the $(\text{La}_{1-x}\text{Y}_x)_{2/3}\text{Ca}_{1/3}\text{MnO}_\delta$ lattice contracts gradually for increasing x , in agreement with our experimental results. In addition, replacing La by Y should not change the $\text{Mn}^{4+}/\text{Mn}^{3+}$ ratio but the difference in ionic size affects the covalent-bond formation. This may explain why we found a smaller Curie temperature and thus larger resistivity for larger x .

It is of interest to note that for the sample with $x=0.4$, the magnetic transition is quite broad and the resistivity is relatively high. These are two common features which can be found also in other samples reported to have very large MR.^{4,5,7} The broad transition indicates some magnetic inhomogeneity. Our x-ray results cannot tell us how the three ions, La, Y, and Ca, arrange in the lattice. If they form clusters, then one may use the model of Gubkin and Perekalina¹⁰ to understand the very large MR effect. If it is the case, then the ferromagnetic tunnel junctions¹¹ may be effective at the grain boundaries. This may explain why the porous samples ($x=0.4$, and 0.5) have higher MR than other compositions.

VII. SUMMARY

A series of polycrystalline bulk samples of $(\text{La}_{1-x}\text{Y}_x)_{2/3}\text{Ca}_{1/3}\text{MnO}_\delta$ were made by standard ceramic process. It is found that the crystallographic structure changes gradually from cubic perovskite to orthorhombic and the lattice constants become smaller for larger x . The change of lattice structure affects the electrical and magnetoresistance effect. The maximum MR was observed for $x \sim 0.4$ with peak MR = 91% at $B=0.85$ T.

Effects of high-temperature annealing on the optical absorption of Ca:YIG films

R. E. Bornfreund and P. E. Wigen

Department of Physics, The Ohio State University, 174 West 18th Avenue, Columbus, Ohio 43210

The effect of high-temperature annealing on the optical properties of a calcium doped yttrium iron garnet (Ca:YIG) film were studied. The optical absorption was examined for a film of $\text{Ca}_{0.18}\text{:YIG}$ reduced in an atmosphere of N_2 at temperatures above 900°C . During the annealing, the optical absorption initially decreased below the as-grown value as expected, but subsequently increased to a value greater than that for the as-grown film as the annealing temperatures were increased. The changes observed in the optical absorption are believed to be due to the introduction of oxygen vacancies in the film as a result of the annealing. Initially, the added oxygen vacancies simply compensate the Ca^{2+} , while successive annealings introduce excess vacancies which lead to a new absorption mechanism. The results of this study and the expected mechanism for the effect are reported. © 1996 American Institute of Physics. [S0021-8979(96)14808-6]

I. INTRODUCTION

Ca:YIG films are currently being investigated as a possible alternative to the dilute magnetic semiconductors. Ca:YIG has many of the properties of a magnetic semiconductor, having resistivities as low as $300\ \Omega\ \text{cm}$ and activation energies of $0.2\text{--}0.4\ \text{eV}$. The wide variety of ions which can be substituted into the garnet structure allow for a tailoring of both the optical and magnetic properties.

At present, the electrical compensation associated with the doping of Ca^{2+} for Y^{3+} is not fully understood. In previous studies, Ca:YIG was subjected to high-temperature annealings in a reducing atmosphere to promote charge compensation by the creation of oxygen vacancies.¹ The previous high-temperature annealing studies observed broad changes in the lattice constant, magnetization, and resistivity of Ca:YIG. Upon annealing in a reducing atmosphere, the room-temperature magnetization has been reported to decrease by as much as 50%, the lattice constant to decrease by as much as $0.032\ \text{\AA}$, and the room-temperature resistivity to increase by several orders of magnitude. These changes have been associated with the formation of oxygen vacancies within the film upon reduction.

A complementary study has been performed to determine the effects of the annealing on the optical properties of the material. In the present study, the optical absorption was examined in a sample annealed in N_2 at temperatures above 900°C . Previous optical studies² of the effects of annealing have limited themselves to temperatures below 900°C . The present work will show that unexpected changes in the optical absorption occur only when annealing temperatures are above 900°C . While unexpected, the changes are consistent with the previous study on the other material properties.

II. EXPERIMENT

The sample under study is a thin garnet film of composition $\text{Ca}_{0.18}\text{:YIG}$. It was grown on a $[111]$ oriented gad-

olinium gallium garnet (GGG) substrate by liquid phase epitaxy (LPE). The growth was performed in a $\text{PbO-B}_2\text{O}_3$ based melt. The thickness of the film was measured by an optical interference method,³ which yielded a thickness for the film of $8.06\ \mu\text{m}$.

Absorption measurements were performed in a Perkin-Elmer Lambda 19 optical spectrometer. All measurements were performed at room temperature. The optical absorption was measured from $190\text{--}2500\ \text{nm}$. The annealings were performed in an Accutherm furnace. The sample was annealed successively in a reducing atmosphere of N_2 at 900 , 930 , 960 , and 1000°C . The annealing was performed for 7 h and the flow rate of the N_2 within the furnace was 2 SCFH. The absorption spectra for the annealings are shown in Fig. 1. For comparison, a second film from the same substrate was annealed in O_2 at 1000°C under the same flow and time conditions. Only insignificant changes in the optical absorption

FIG. 1. Optical absorption of $\text{Ca}_{0.18}\text{:YIG}$ for a film successively annealed for 7 h at the indicated temperatures in a N_2 atmosphere.

compared to the as-grown spectra were found and therefore, this spectrum was left off the graph for the sake of clarity.

III. RESULTS AND DISCUSSION

The optical absorption spectra shown in Fig. 1 have two features at roughly 607 and 910 nm. These features have been identified in YIG as crystal field transitions.^{4,5} The transition at 607 nm is the ${}^6A_1({}^6S) \rightarrow {}^4T_1({}^4G)$ transition occurring within the tetrahedral iron crystal field levels, while the other feature occurring at 910 nm is the ${}^6A_{1g}({}^6S) \rightarrow {}^4T_{1g}({}^4G)$ transition occurring within the octahedral crystal field levels. No shift in the position of these transitions is observed during the course of the annealing study.

Upon annealing the sample, only shifts in the background absorption A , are observed. With a wavelength of 1000 nm chosen as a reference, A decreases roughly 50% upon annealing at 900 °C in N_2 . Subsequent annealings at higher temperatures resulted in an overall increase in A . An annealing in N_2 at 930 °C resulted in A increasing to 75% of the original sample's value. The optical absorption continued to increase when the film was annealed at 960 °C, with the value of A close to that of the as-grown film. Of note is the observation that the value of A for the 960 °C annealing goes from being smaller in magnitude than the as-grown value at wavelengths longer than 850 nm to larger than the as-grown value at wavelengths smaller than 850 nm. Annealing in 1000 °C results in an increase in A of 76% over the as-grown value at 1000 nm and the introduction of a broad tail to the optical band edge.

The initial decrease in A with reduction is consistent with previously reported decreases in A upon reduction in a boiling $FeCl_2$ solution.² This is due to the formation of a sufficient number of oxygen vacancies to optically and electrically compensate the absorption center associated with the holes produced by Ca^{2+} doping in YIG. The subsequent increase in A would seem to be due to the dominance of a new absorption mechanism due to the additional oxygen vacancies.

As mentioned earlier, the transitions at 607 and 910 nm do not shift in position or broaden with annealing. The introduction of a broad tail to the band edge and the introduction of oxygen vacancies with annealing suggests a modification of the $2p$ valence band, but details of the new absorption center are not known at this time.

In order to eliminate the possibility that thermal migration of the ions produced the observed effects, a second film was annealed in O_2 at 1000 °C for 7 h. Although not shown for the sake of clarity, little change was observed in the absorption spectra of the oxidized sample compared to its as-grown state. This is in agreement with previous measurements of the magnetization, electrical resistivity, and lattice constant in which insignificant changes were observed.¹

IV. CONCLUSIONS

Unexpected shifts in the absorption spectra have been observed in Ca:YIG films reduced in a N_2 atmosphere at temperatures above 900 °C. The shifts in the optical absorption are observed in association with the formation of oxygen vacancies within the crystal lattice through the high-temperature reduction. A broadening of the band edge for the sample reduced at 1000 °C can be attributed to a modification of the valence band structure due to the excess oxygen vacancies introduced.

In $\text{Zn}_{1-x}\text{Mn}_x\text{Se}$, $\text{Mn}^{2+} d \rightarrow d^*$ transitions were found to induce giant Faraday rotation, and peaks of the Faraday rotation spectra were red-shifted linearly with increasing Mn composition. Through studying the magneto-optical transition variation with Mn composition, the Mn composition can be determined. Results from the Faraday rotation analysis were compared with the x-ray diffraction data and were found in good agreement with each other. © 1996 American Institute of Physics. [S0021-8979(96)14908-2]

I. INTRODUCTION

The diluted magnetic semiconductor $\text{Zn}_{1-x}\text{Mn}_x\text{Se}$ is formed by random substitution of Mn for Zn atoms. It shows some interesting magnetic and magneto-optical properties,¹ such as the giant Faraday rotation.¹⁻³ This made it a promising candidate for fabricating some magneto-optical devices, such as magnetic field sensors, magneto-optical isolators, etc., and much attention has been paid to the study of the material in recent investigations.

The magneto-optical properties and lattice parameter of $\text{Zn}_{1-x}\text{Mn}_x\text{Se}$ are tunable by varying the Mn composition. Yoder-short, Debska, and Furdyna⁴ had quantitatively given the data and equations for the lattice parameter as a function of Mn composition x by using both electron probe microanalysis and x-ray diffraction methods which can be used to determine the Mn composition precisely. In terms of equations of Ref. 4, therefore, in most cases the Mn composition can be simply determined by measuring the lattice parameter through the x-ray diffraction technique.

In this paper, we provide a new method to determine the Mn composition in $\text{Zn}_{1-x}\text{Mn}_x\text{Se}$. We found that the giant Faraday rotations are actually induced by $\text{Mn}^{2+} d \rightarrow d^*$ transitions and peaks of Faraday rotation spectra are linearly red-shifted with Mn composition. Here, an empirical formula about the variation of $\text{Mn}^{2+} d \rightarrow d^*$ transitions with composition is presented, and the Mn composition can be readily determined from the Faraday rotation data for these samples. Results were compared with those obtained from x-ray diffraction data.

II. EXPERIMENT AND RESULTS

$\text{Zn}_{1-x}\text{Mn}_x\text{Se}$ film samples in this experiment were grown on (100)-oriented GaAs by the molecular beam epitaxy method (MBE) at the temperature of 280 °C. Using the equation given in Ref. 4, Mn compositions were determined by x-ray diffraction measurements. The x-ray diffraction was performed with copper radiation and the diffraction pattern was measured in 2θ from 60° to 70°. The spectra of Faraday rotation were measured at room temperature and 10 kG magnetic field with a rotating analyzer type Kerr apparatus,⁵ since GaAs is opaque in the visible range and thin

$\text{Zn}_{1-x}\text{Mn}_x\text{Se}$ films are almost transparent in the photon energy range below the interband energy gap. The photon energy was scanned from 1.5 to 3.5 eV with 0.01 eV interval, and the incidence angle of light was about 2°.

$\text{Zn}_{1-x}\text{Mn}_x\text{Se}$ alloys have many phases. They exhibit zinc-blende structure for $x < 0.30$ and wurtzite structure for $0.30 < x < 0.57$. When x is higher than 0.57, multiple phases coexist in the alloys. Both zinc-blende and wurtzite structures are tetrahedrally coordinated, and the local environment of the tetrahedron formed by like atoms is identical so it is meaningful to consider the mean cation-cation distance d_c over the entire range of existence of $\text{Zn}_{1-x}\text{Mn}_x\text{Se}$.⁴ The cation-cation distance d_c is a function of composition x , which can be written as

$$d_c = 4.005 + 0.1748x. \quad (1)$$

Figure 1 shows x-ray diffraction patterns of the $\text{Zn}_{1-x}\text{Mn}_x\text{Se}$ films grown on (100) GaAs substrates. The right sharp peak corresponds to (400) plane of GaAs, and the weaker one to that of $\text{Zn}_{1-x}\text{Mn}_x\text{Se}$ films. From Bragg reflection formula, we have

$$2d_{400} \sin \theta = \lambda, \quad (2)$$

where d_{400} is the interplanar distance between (400) planes, θ is the diffraction angle, and λ is the wavelength of copper radiation and is equal to 1.5406 Å. The cation-cation distance d_c is related to d_{400} by the following equation:

$$d_c = 2\sqrt{2}d_{400}, \quad (3)$$

so it is easy to determine the Mn composition by Eqs. (1)–(3).

Figure 2 shows the spectra of Faraday rotation Θ_F for the $\text{Zn}_{1-x}\text{Mn}_x\text{Se}$ samples. There are two observable peaks labeled as E_a at energy of 2.4 to ~2.55 eV, and E_b at ~2.6 eV for all samples, and another peak labeled as E_c with an energy of ~2.72 eV for the sample having higher composition. With increasing Mn composition, the positions E_a , E_b , and E_c shift to the lower energy end. The peaks at E_a and E_b come close to each other, and finally combine into a single broad peak.

We assign E_a , E_b , and E_c to the $\text{Mn}^{2+} d \rightarrow d^*$ multiplet transitions.² E_a corresponds to ${}^6A_1({}^6S) \rightarrow {}^4T_2({}^4G)$ transi-

FIG. 1. X-ray diffraction patterns of the $\text{Zn}_{1-x}\text{Mn}_x\text{Se}$ film samples a, b, c, d, and e grown on (100)-oriented GaAs. The sharp peaks correspond to (400) plane of GaAs, and the broad ones correspond to that of $\text{Zn}_{1-x}\text{Mn}_x\text{Se}$ films. Mn concentrations determined by the broad peaks of $\text{Zn}_{1-x}\text{Mn}_x\text{Se}$ films for a, b, c, d, and e samples are 0.06, 0.11, 0.14, 0.17, and 0.21, respectively.

tion, E_b to ${}^6A_1({}^6S) \rightarrow [{}^4A_1({}^4G), {}^4E({}^4G)]$, and E_c to ${}^6A_1({}^6S) \rightarrow {}^4T_2({}^4P)$. The red-shifts of E_a and E_b in $\text{Zn}_{1-x}\text{Mn}_x\text{Se}$ were clearly found to be linear with composition, which can be expressed as

$$E_a(300 \text{ K}) = (2.6132 - 1.1370x) \text{ eV}, \quad (4)$$

$$E_b(300 \text{ K}) = (2.6934 - 0.6200x) \text{ eV}, \quad (5)$$

while E_c at ~ 2.72 eV varies less with composition. The disappearing of the E_c peak for lower composition samples

FIG. 2. The spectra of Faraday rotation Θ_F of the $\text{Zn}_{1-x}\text{Mn}_x\text{Se}$ film samples a, b, c, d, and e measured at room temperature and 10 kG magnetic field. Mn concentrations determined by the E_b peaks of $\text{Zn}_{1-x}\text{Mn}_x\text{Se}$ films for a, b, c, d, and e samples are 0.05, 0.10, 0.15, 0.18, and 0.21, respectively.

TABLE I. The comparison of Mn composition obtained from the x-ray diffraction technique and Faraday rotation analysis for $\text{Zn}_{1-x}\text{Mn}_x\text{Se}$ film samples a, b, c, d, and e.

Samples	a	b	c	d	e
x-ray diffraction	0.06	0.11	0.14	0.17	0.21
Faraday analysis	0.05	0.10	0.15	0.18	0.21

was due to the stronger interband absorption occurring at the interband gap energy E_g that is $\leq E_c$ to make Faraday rotation spectra be cutoff at E_g . As we have known, the interband gap E_g also varies with composition. For $\text{Zn}_{1-x}\text{Mn}_x\text{Se}$, $E_g(x)$ at room temperature it can be written as

$$E_g(300 \text{ K}) = (2.71 + 0.19x) \text{ eV}. \quad (6)$$

Unlike E_a and E_b , E_g shows bowing effects, i.e., shifts to lower then higher energies with increasing Mn concentration as indicated in Ref. 1. From Eqs. (4)–(6), it is obvious that E_a and E_b are always lower than E_g in the entire composition range, but $E_c(\sim 2.72 \text{ eV})$ will be higher than E_g for lower composition samples. The E_c transition will be masked by E_g transitions for these samples, resulting in the disappearance of the E_c peak.

The Faraday rotation peak at E_b is considerably large and sharp. Therefore, if the position of E_b can be measured precisely, the composition can be determined relatively easily by using Eq. (5). In our experiment, the $\text{Zn}_{1-x}\text{Mn}_x\text{Se}$ samples were characterized by both the x-ray diffraction technique and Faraday rotation analysis method. Mn compositions were determined by using Eqs. (1)–(3) with x-ray diffraction data and by using Eq. (5) with Faraday rotation data, respectively. The results from the two methods are compared and are shown to be in good agreement as seen in Table I.

III. CONCLUSION

In this experiment, we found that the giant Faraday rotation induced by $\text{Mn}^{2+} d \rightarrow d^*$ multiplet transitions in $\text{Zn}_{1-x}\text{Mn}_x\text{Se}$ can be used as a method to determine Mn composition. The Faraday rotation peak at $E_b(\sim 2.6 \text{ eV})$ is considerably strong and sharp at room temperature, and $E_b(x)$ is found to be given by $2.6934 - 0.6200x \text{ eV}$. The precise E_b data can be readily obtained from Kerr apparatus, and then the compositions are immediately obtained. The compositions determined from both x-ray diffraction technique and Faraday rotation analysis were compared and were in good agreement with each other.

Microstructural properties of (ZnSe/FeSe) and (ZnSe/MnSe) diluted magnetic semiconductor superlattices (abstract)

K. Park^{a)} and L. Salamanca-Riba

Department of Materials and Nuclear Engineering, University of Maryland, College Park, Maryland 20742

B. T. Jonker

Naval Research Laboratory, Washington, DC 20375

Recently, there has been increased research activity on Fe-, Mn-, and Co-based diluted magnetic semiconductors (DMS) because of their interesting magneto-optical properties. Potential applications of DMS usually require thin films with a high degree of structural perfection, and high quality single crystal epilayers of $\text{Zn}_{1-x}\text{Fe}_x\text{Se}$ and $\text{Zn}_{1-x}\text{Co}_x\text{Se}$ have been grown by molecular beam epitaxy (MBE).^{1,2} In this work, the microstructural properties of (ZnSe/FeSe) and (ZnSe/MnSe) DMS superlattices grown on (001) GaAs substrates by MBE have been investigated using transmission electron microscopy. High-quality (ZnSe/FeSe) superlattices were grown by introducing a ZnSe buffer layer on the GaAs substrate prior to the growth of the superlattice. In contrast, nominal (ZnSe/FeSe) superlattices grown directly without a buffer layer on the substrate showed evidence for interdiffusion between the constituent layers of the superlattice. Chemical ordering of the Zn and Fe atoms was also observed in the resultant $\text{Zn}_{1-x}\text{Fe}_x\text{Se}$ alloys along the [001] and [110] directions. This ordered structure corresponds to the CuAu-I type structure. In contrast, the (ZnSe/MnSe) superlattices did not show interdiffusion, but contained many microtwins and 60°-type misfit dislocations. The MnSe layer in the (ZnSe/MnSe) superlattices existed as a zinc-blende structure. © 1996 American Institute of Physics. [S0021-8979(96)46908-7]

Polaron-polaron interactions in diluted magnetic semiconductors

The bound magnetic polaron (BMP) is the characteristic collective state of diluted magnetic semiconductors. Isolated BMP are well understood, but their interactions are only beginning to be explored. Recent polaron magnetization experiments on *p*-ZnMnTe suggest a *ferromagnetic* polaron-polaron interaction, in contrast to the invariably *antiferromagnetic* impurity exchange interaction in conventional semiconductors. To investigate this question theoretically, we have developed a simplified model of polaron pairs whose central feature is competition between the usual, antiferromagnetic, virtual-hopping interaction, and the loss of carrier-magnetic ion exchange energy, by intermediate ions, when the polaron moments are antiferromagnetically aligned. The model is sufficiently simple that its partition function can be calculated in detail. With reasonable parameters, it predicts a ferromagnetic polaron-polaron interaction at low temperatures. © 1996 American Institute of Physics. [S0021-8979(96)15008-7]

The bound magnetic polaron (BMP) is the characteristic collective state of diluted magnetic semiconductors (DMS). BMP is created by the exchange interaction of localized carriers with magnetic ions (often Mn^{2+} in II-VI semiconductors) within the carrier orbit.¹ To date, BMP studies have generally been done on dilute samples where polaron-polaron interactions are negligible. Recently, however, polaron magnetization experiments on heavily doped, *p*-type ZnMnTe have given hints of a weak *ferromagnetic* polaron-polaron interaction,² whereas in conventional nonmagnetic semiconductors impurity-impurity interactions are invariably antiferromagnetic.³ To explain this unexpected result, we have studied a simplified model of polaron pairs whose central feature is competition between the usual, antiferromagnetic interaction due to virtual hopping of carriers, and the loss of carrier- Mn^{2+} exchange energy by intermediate magnetic ions when the polaron moments are antiferromagnetically aligned. With reasonable parameters, the model predicts a ferromagnetic polaron-polaron interaction at low temperatures. This result suggests the possibility of polaron ferromagnetism in heavily doped (albeit insulating), *p*-type II-VI DMS.

The BMP problem is complicated, theoretically, by the fact that the exchange field experienced by a Mn^{2+} ion is proportional to the square of the carrier wave function at its site—therefore, varies rapidly with Mn^{2+} ion position. This spatial variation precludes an exact, quantum mechanical evaluation of the single polaron partition function, and makes the polaron pair problem intractable. To avoid this difficulty we have extended an exactly soluble model of the single polaron, developed by Ryabchenko and Semenov (RS),⁴ to the polaron pair case. RS make the seemingly drastic approximation of replacing the spatially varying wave function by a constant for $r \leq R_0$ and zero for $r > R_0$. The carrier- Mn^{2+} exchange interaction then takes the simple form

$$H = K \sum_{(R_i < R_0)} (s \cdot S_i) = K(s \cdot S) \equiv \frac{K}{2} [(s + S)^2 - S^2 - s^2], \quad (1)$$

where S_i is the Mn^{2+} spin at site R_i , s is the carrier spin (assumed to be $1/2$) and $S = \sum_i (S_i)$. Here, S^2 , s^2 , and $(s + S)^2$ are constants of the motion so, for a given S , Eq. (1) immediately gives the energies. For $s = 1/2$ there are two levels corresponding to $|S + s| = (S \pm 1/2)$ with energies $E_+ = KS/2$ and $E_- = -K(S + 1)/2$. When $S \gg 1$, the most probable situation for polarons at low temperature, these states are highly degenerate because there are many ways of combining the Mn^{2+} spins (with $R_i < R_0$) to give total spin S . The degeneracies are lifted when the carrier wave function varies in space so, in detail, the eigenfunctions of the RS model are quite different from those of the true Hamiltonian. Nevertheless, when averaged over possible values of S , Eq. (1) gives an excellent approximation to the BMP partition function⁵ if the parameters K and R_0 are determined with the Feynman variational theorem.⁶

Granting that the RS model gives a good description of the single polaron, how can it be extended to treat the polaron pair? We assume, as in Liu's experiments, that polarons are far apart (spacing d) compared to the Bohr radius (a^*) of the localized carrier states. It is then natural, as illustrated in Fig. 1, to divide Mn^{2+} spins into three categories—those associated with polaron 1 ($|R_i - R_1| < R_0$), those associated with polaron 2 ($|R_i - R_2| < R_0$), and intermediate Mn^{2+} spins that feel a weaker exchange field from *both* carriers. In the spirit of the RS model we then choose a Hamiltonian for the pair problem of the form

$$H = K[(s_1 \cdot S_1) + (s_2 \cdot S_2)] + K'[(s_1 + s_2) \cdot S_3] + J(s_1 \cdot s_2). \quad (2)$$

The first term in this equation describes two polarons without interaction, the second is a polaron-polaron coupling induced by intermediate Mn^{2+} (with total spin S_3) that can be ferromagnetic if the carrier spins are in a triplet state. Finally, $J(s_1 \cdot s_2)$ is the standard, antiferromagnetic interaction induced by virtual hopping of carriers from one site to the other. In the limit we are considering ($a^*/d \ll 1$), the parameters K' and J are both exponentially smaller than K . For acceptor BMP in ZnMnTe, $K \approx 2$ meV. K' and J are of order

POLARON PAIR MODEL

FIG. 1. Schematic of polaron pair model.

$$K' \cong K e^{-d/a^*} \quad \text{and} \quad J \cong \frac{e^2 a^*}{\epsilon d^2} (e^{-2d/a^*}). \quad (3)$$

To lowest order (ignoring K' and J terms) the two polaron problem has four, highly degenerate energy levels: $E = (K/2)(S_1 + S_2)$, $E = (K/2)[S_1 - (S_2 + 1)]$, $E = -(K/2)[(S_1 + 1) - S_2]$, and $E = -(K/2)[(S_1 + 1) + (S_2 + 1)]$. At low temperatures, where the most probable values of S_1 and S_2 are sizable, these manifolds are separated from one another by energies of order 20–30 meV,⁷ with only the last one having substantial occupation. Off-diagonal matrix elements of the K' and J operators between these manifolds produce only weak, second order perturbations. Thus, in calculating the effect of the K' and J operators, we need only include matrix elements *within* the ground state manifold.

BMPs have many degrees of freedom—of order $(6)^N$ where N is the number of Mn^{2+} ions involved. Thus, even at low temperatures, their properties are statistically determined. For that purpose we need the partition function of the model Hamiltonian. A fully quantum mechanical calculation is complicated, but unnecessary at low temperatures. In that limit (below about 20 K in ZnMnTe) the individual polarons have fully formed by aligning all Mn^{2+} spins within their orbits. Each has a sizable spin; $\langle S_1 \rangle = \langle S_2 \rangle \approx 50$. Intermediate Mn^{2+} spins (those in S_3) are only partially aligned but, because there are many of them, fluctuations produce a sizable value of $\sqrt{\langle S_3^2 \rangle} \approx \sqrt{N_3}$. Thus, the three spin populations all have large total spin, implying that a classical approximation can be used in calculating averages over S_1 , S_2 , and S_3 . Henceforth, we integrate over these variables in evaluating the partition function, but retain the quantum mechanical properties of the two carrier spins (s_1 and s_2).

In this semiclassical approximation the wave functions of the unperturbed polaron pair (assuming $K' = J = 0$) are: $\alpha_1(1)\alpha_2(2)$, $\alpha_1(1)\beta_2(2)$, $\beta_1(1)\alpha_2(2)$, $\beta_1(1)\beta_2(2)$, where $\alpha_{1,2}$ and $\beta_{1,2}$ are spinors whose quantization axes are parallel to S_1 and S_2 , respectively. The state $\varphi_0 = \beta_1(1)\beta_2(2)$ with (classical) energy $-K(S_1 + S_2)/2$ corresponds to the ground state manifold previously discussed. It is the only state occupied at low temperature, so the effects of the K' and J perturbations are determined, as discussed above, by the diagonal matrix elements

$$M_{K'} = \langle \varphi_0 | H_1 | \varphi_0 \rangle = \frac{-K'}{2} \left[\frac{S_2 S_1 + S_1 S_2}{S_1 S_2} \right] \cdot S_3 \quad (4)$$

and

$$M_J = \langle \varphi_0 | H_2 | \varphi_0 \rangle = \frac{J}{4} \left(\frac{S_1 \cdot S_2}{S_1 S_2} \right) = \frac{J \mu_{12}}{4}. \quad (5)$$

Here, μ_{12} is the cosine of the angle between S_1 and S_2 . The partition function then takes the form $Z = Z_P(6)^{N_{\text{ext}}}$ where N_{ext} is the number of Mn^{2+} ions external to the interaction region and the polaron pair partition function is

$$Z_P = \int \int \int \left\{ D_{N_1}(S_1) D_{N_1}(S_2) D_{N_3}(S_3) e^{\beta K/2(S_1 + S_2)} \right. \\ \times (e^{-\beta J \mu_{12}/4}) \exp \left[\beta K'/2 \frac{|S_2 S_1 + S_1 S_2|}{S_1 S_2} \mu_3 S_3 \right] \Bigg\} \\ \times d^3 S_1 d^3 S_2 d^3 S_3. \quad (6)$$

Here, $D(S)$ is the number of ways of combining N Mn^{2+} spins to give total spin S . Integrating over $d\mu_3$ and using the fact

$$\frac{|S_2 S_1 + S_1 S_2|}{S_1 S_2} = \sqrt{2}(1 + \mu_{12})^{1/2}, \quad (7)$$

we find

$$Z_P = 4\pi \int \int \int \left\{ D_{N_1}(S_1) D_{N_1}(S_2) D_{N_3}(S_3) e^{\beta K/2(S_1 + S_2)} \right. \\ \times (e^{-\beta J \mu_{12}/4}) \frac{\sinh \left[\frac{\beta K'(1 + \mu_{12})^{1/2} S_3}{\sqrt{2}} \right]}{\left[\frac{\beta K'(1 + \mu_{12})^{1/2} S_3}{\sqrt{2}} \right]} \Bigg\} \\ \times d^3 S_1 d^3 S_2 d^3 S_3. \quad (8)$$

The dS_3 integration is simplified by the relation

$$2\pi S_3 D(S_3) = -\frac{d}{dS_3} [D_z(S_3)], \quad (9)$$

where $D_z(S_3)$ is the number of ways of combining N_3 Mn^{2+} spins to give total $S_z = S_3$. This formula is the classical analog of a quantum mechanical relation derived by Kasuya and Yanase.⁸ After integrating by parts, Eq. (8) takes the form

$$Z_P = 2 \int \int \int \left\{ D_{N_1}(S_1) D_{N_1}(S_2) D_z(S_3) e^{\beta K/2(S_1 + S_2)} \right. \\ \times e^{-\beta J \mu_{12}/4} \cosh \left[\frac{\beta K'(1 + \mu_{12})^{1/2}}{\sqrt{2}} \right] \Bigg\} d^3 S_1 d^3 S_2 dS_3. \quad (10)$$

Here

$$D_z(S) \equiv \text{Tr} \left\{ \delta \left[S - \sum_{j=1}^N (S_{jz}) \right] \right\}, \quad (11)$$

and the dS_3 integration can be evaluated via the method described in Ref. 1. The result is

$$\begin{aligned}
Z_P &= 2(6)^{N_3} \int \int \left\{ D_{N_1}(S_1) D_{N_1}(S_2) e^{\beta K/2(S_1+S_2)} e^{-\beta J \mu_{12}/4} \right. \\
&\quad \times \left[F\left(\frac{\beta K'}{\sqrt{2}} \sqrt{1+\mu_{12}}\right) \right]^{N_3} \Big\} d^3 S_1 d^3 S_2 \\
&= 2\pi Z_1 Z_2 (6)^{N_3} \int_0^{\sqrt{2}} e^{-\beta J/4(x^2-1)} \left[F\left(\frac{\beta K' x}{\sqrt{2}}\right) \right]^{N_3} x dx,
\end{aligned} \tag{12}$$

where we have made the change of variables $\mu_{12} = (x^2 - 1)$. Z_1 and Z_2 are the partition functions of polarons 1 and 2 without interaction. F is one sixth the single Mn^{2+} ion partition function

$$F(y) \equiv \frac{1}{6} \left[\frac{\sinh(3y)}{\sinh(y/2)} \right]. \tag{13}$$

We now have an analytic approximation to the partition function from which one can determine all thermodynamic properties, such as $\langle \mu_{12} \rangle$. To evaluate it, note that the integrand of Eq. (12) is the relative probability of finding $\mu_{12} = (x^2 - 1)$. Therefore

$$\langle \mu_{12} \rangle = \frac{\int_0^{\sqrt{2}} e^{-\beta J/4(x^2-1)} \left[F\left(\frac{\beta K' x}{\sqrt{2}}\right) \right]^{N_3} (x^2 - 1) x dx}{\int_0^{\sqrt{2}} e^{-\beta J/4(x^2-1)} \left[F\left(\frac{\beta K' x}{\sqrt{2}}\right) \right]^{N_3} x dx}. \tag{14}$$

Equation (14) has been evaluated for representative values of the ratio, (K'/J) and number (N_3) of intervening Mn^{2+} ions, as a function of temperature. Figure 2 shows a typical result of these calculations. The various curves in this figure reflect different degrees of competition between the K' and J interactions. When $(K'/J) = 0$ there is no competition so that the polaron spins are antiferromagnetically aligned, $\langle \mu_{12} \rangle < 0$, at all temperatures.

As this ratio increases, the polaron pair behaves ferromagnetically in an increasing range of temperatures above $T = 0$. For intermediate values of (K'/J) , the crossover from ferromagnetic to antiferromagnetic behavior is at $kT \approx \frac{1}{6}(N_3 K')^2/J$.

We propose a simplified, soluble model of a pair of BMP, designed to capture the essence of the interaction between polarons in diluted magnetic semiconductors. We are able to analytically calculate the partition function of the model at low temperatures where each carrier polarizes Mn^{2+} spins within its orbit, but the interpolaron interaction may be large or small compared to the temperature. Our calculations are approximate in two ways. The more important of the two is the constant wave function approximation, as used by RS for the single polaron problem. For the single polaron it has been tested and shown to give results within 10% of those measured.⁵ Preliminary results using optimized Hamiltonians for the polaron pair problem suggest that Hamiltonian (2) is a reasonable approximation to it as well.⁹ Moreover, it is encouraging that, with reasonable parameters,

FIG. 2. Plots of the thermal average of the cosine of the angle between polaron spins, $\langle \mu_{12} \rangle$, vs temperature for $N_3 = 20$ and several values of the ratio (K'/J) .

the model favors a ferromagnetic polaron-polaron interaction whose size is not inconsistent with Liu's results.

The second approximation is our neglect of next-nearest-neighbor Mn^{2+} - Mn^{2+} exchange interactions. Nearest-neighbor interactions are included by the use of an effective Mn^{2+} concentration $\bar{x} = x(1-x)^{12,1}$. Next-nearest-neighbor interactions become important at about 1 K. Thus, polaron interaction effects should be partially suppressed when the carrier- Mn^{2+} exchange field falls below 1 K. For the intervening Mn^{2+} ions this effect becomes important when

$$\frac{2(bN_0)}{\pi N_0(a^*)^3} e^{-d/a^*} \approx 10^{-4} \text{ eV}, \tag{15}$$

where (bN_0) is the hole- Mn^{2+} exchange interaction, about 1.2 eV in ZnMnTe . With $a^* = 10^{-7}$ cm, Eq. (15) predicts that suppression begins for $(d/a^*) > 6$, which is close to the most probable interpolaron distance ratio $(d/a^* = 7)$ in a sample containing 7×10^{17} acceptors per cc. We conclude that our neglect of next-nearest-neighbor Mn^{2+} interactions is barely justified in Liu's experiments. It is probable, therefore, that the weak ferromagnetic polaron-polaron interaction he observes is due to a fraction of the pairs whose separation is smaller than the average, but with a substantially larger value of K' .

Hybrid pole pieces for permanent magnets

M. G. Abele and J. H. Jensen

Department of Radiology, New York University School of Medicine, New York, New York 10016

Highly uniform magnetic fields for nuclear-magnetic-resonance imaging require accurate design of the pole pieces of a permanent magnet structure. We present a mathematical theory of pole pieces viewed as filters that eliminate selected harmonics of an expansion of the field distortion. Previous work has discussed two types of filters: active pole pieces and passive pole pieces. These are reviewed and a third type of filter, the hybrid pole piece, is introduced. The hybrid pole piece provides distinct advantages by combining features of both active and passive pole pieces. © 1996 American Institute of Physics. [S0021-8979(96)52608-6]

I. INTRODUCTION

Permanent magnets can be designed to generate highly uniform fields for nuclear-magnetic-resonance imaging in medicine. Sophisticated design approaches¹ are required not only to minimize the size and weight of a magnet, but also to compensate for the poor tolerances of the magnetic characteristics of available materials. This article presents a hybrid design for the pole pieces of a magnet that acts as a filter to eliminate the spatial harmonics of the field distortion. The design follows a precise mathematical formulation that applies to the design phase as well as to the final shimming of the magnet.

II. FILTER EQUATIONS

Figure 1 shows the schematic of a permanent magnet. The interface between the two pole pieces and the gap are assumed to be parallel plane surfaces at a distance $2y_0$ from each other. Assume a reference cylinder of radius r_i that contains the region of interest where the field must satisfy the required uniformity condition. If the two plates are composed of a material of infinite permeability, the magnetostatic potential within the reference cylinder can be expanded in the series²

$$\begin{aligned} \Phi(r, \psi, y) = & \Phi_2 + \frac{y_0 + y}{2y_0} \Phi_0 \\ & + \sum_{m,n} I_m \left(n\pi \frac{r}{2y_0} \right) \sin \left(n\pi \frac{y_0 + y}{2y_0} \right) \\ & \times (a_{m,n,1} \cos m\psi + a_{m,n,2} \sin m\psi), \end{aligned} \quad (2.1)$$

where r, ψ, y are cylindrical coordinates with the axis y being coaxial to the reference cylinder, and I_m is the modified Bessel function of the first kind. Φ_0 is the potential difference between the two plates, and Φ_2 is the potential of the plate located at $y = -y_0$. The first two terms on the right-hand side of Eq. (2.1) correspond to a uniform field oriented along the axis y , and the series over the m, n harmonics of

amplitudes $a_{m,n,1}$ and $a_{m,n,2}$ is the field distortion. In most cases, $a_{m,n,1}$ and $a_{m,n,2}$ decrease rapidly with increasing m and n , and the distortion is primarily due to just a small number of low-order harmonics.

The elimination of the unwanted harmonics of the spectrum defined by Eq. (2.1) is provided by a filter structure located on the two plates outside the reference cylinder. The principle of the design of the filter is an alteration of the potentials of the plates in the region between concentric circles of radii r_i and r_e . With a proper choice of this alteration, the harmonics of the field distortion in Eq. (2.1) may be cancelled.

Let $\delta\Phi_+(r, \psi)$ be the potential shift on the upper plate from the value $\Phi_2 + \Phi_0$, and let $\delta\Phi_-(r, \psi)$ be the shift on the lower plate from Φ_2 . The shifts required to cancel the field distortion satisfy, to a good approximation, the system of integral equations²

FIG. 1. Schematic of a permanent magnet. The shaded regions are the pole pieces, the arrows indicate the direction of magnetization in the magnetic material, and the heavy external line represents the yoke.

$$\frac{\pi}{8y_0^2}(-1)^n n \int_0^{2\pi} d\psi \int_{r_i}^{r_e} r K_m \left(n\pi \frac{r}{2y_0} \right) \times [\delta\Phi_+(r, \psi) - (-)^n \delta\Phi_-(r, \psi)] \begin{pmatrix} \cos m\psi \\ \sin m\psi \end{pmatrix} dr$$

$$= (1 + \delta_{m0}) \begin{pmatrix} a_{m,n,1} \\ a_{m,n,2} \end{pmatrix}, \quad (2.2)$$

for $m = 0, 1, 2, \dots$ and $n = 1, 2, 3, \dots$, and where K_m is the modified Bessel function of the third kind. The filter equations (2.2) are exact in the limit that the radial dimension of the plates tends to infinity. K_m behaves asymptotically as

$$K_m(x) \sim \left(\frac{2}{\pi x} \right)^{1/2} e^{-x} \quad (x \gg 1). \quad (2.3)$$

Because of this rapid decrease of K_m with increasing values of its argument, Eq. (2.2) implies that the larger the value of n is for a harmonic the more its cancellation will tend to be dominated by the behavior of the shifts $\delta\Phi_{\pm}$ close to $r = r_i$.

III. FILTER STRUCTURES

The filter equations (2.2) do not have a unique solution. A solution is determined by selecting a geometry for the filter structure. Consider, as an example, an axisymmetric magnet whose geometry is independent of ψ and is symmetric with respect to the plane $y=0$. Assume, to begin with, perfect geometrical and magnetic characteristics of the materials, in which case the two plates acquire equal and opposite potentials, i.e.,

$$\Phi_2 = -\frac{1}{2}\Phi_0, \quad (3.1)$$

and the potential shifts may be assumed to obey the condition

$$\delta\Phi_+(r) = -\delta\Phi_-(r). \quad (3.2)$$

As a consequence, the expansion (2.1) reduces to the $m=0$, $n=2, 4, 6, \dots$ terms.

A solution of the filter equations (2.2) intended to cancel a given number of harmonics l is obtained by dividing the interval between $r = r_i$ and $r = r_e$ on both plates into l concentric rings each with a potential shift $\pm\delta\Phi_k$, $k = 1, \dots, l$ (+ for the upper plate and - for the lower plate). Equation (2.2) then reduces to

$$\frac{\pi}{2y_0} \sum_{k=1}^l C_{n,k} \delta\Phi_k = a_{0,n,1}, \quad n=2, 4, \dots, 2l. \quad (3.3)$$

The coefficients $C_{n,k}$ are given by

$$C_{n,k} = r_k K_1 \left(n\pi \frac{r_k}{2y_0} \right) - r_{k-1} K_1 \left(n\pi \frac{r_{k-1}}{2y_0} \right), \quad (3.4)$$

where r_k is the inner radius of the k th ring with $r_k < r_{k-1}$ and $r_0 \equiv r_e$. An optimization of the l ring filter structure results in a radial dimension $\Delta r_k \equiv r_{k-1} - r_k$ for each ring,

$$\Delta r_k \sim \frac{y_0}{k\pi}. \quad (3.5)$$

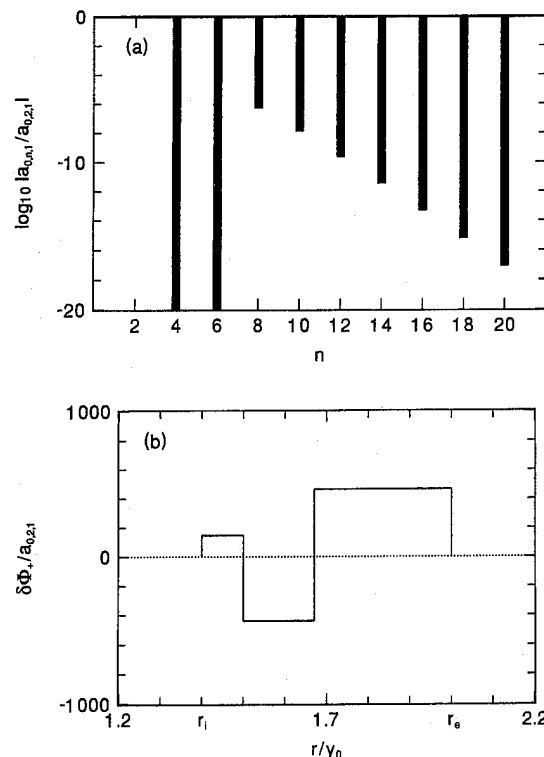

FIG. 2. (a) Spectrum of the field generated by an axisymmetric three-ring filter designed to cancel the $n=2$ harmonic without generating $n=4, 6$ harmonics (the odd-order harmonics are zero by symmetry and are not shown). (b) $\delta\Phi_+$ in the three rings.

By virtue of Eq. (3.5), the radial dimension of the filter structure diverges for $l = \infty$. This is a consequence of the fact that the filter should enclose completely the region of interest in order to cancel the full spectrum of the field distortion. Therefore, the filter must be limited to the cancellation of a finite number of harmonics, usually chosen to be the lowest order in n .

FIG. 3. A hybrid pole piece (shaded region) designed to cancel the $n=2, 4$ harmonics. Each pole piece has one active ring, which are magnetized in the direction shown by the small arrows. The dashed line is the boundary of region of 100 ppm uniformity, and the dotted line is the boundary of the region of 10 ppm uniformity. The solid lines between the pole pieces represent equipotential surfaces.

Figure 2(a) shows the spectrum of the field within a cylinder of radius $r_i = 1.4y_0$ generated by a three-ring filter designed to cancel the $n=2$ harmonics without generating $n=4,6$ harmonics. The distribution of $\delta\Phi_+$ in the rings is plotted in Fig. 2(b), showing a sign inversion of $\delta\Phi_+$ in adjacent rings. Such a sign inversion is typical of filters designed to cancel a single harmonic and is a result of all the coefficients $C_{n,k}$ being positive.

For an active pole piece, the filter is constructed by embedding magnetic material into the plates. In particular, to generate the uniform shifts $\pm\delta\Phi_k$ determined by Eqs. (3.3), magnetic material is sandwiched between the main body of the plate and magnetically insulated concentric plates of high permeability material with dimensions corresponding to the l rings.²⁻⁴ This arrangement permits the shifts to be easily adjusted by altering the amount of magnetic material for each ring.

In a traditional magnet design, the compensation of the field distortion is provided by the geometry of the pole pieces, which are equipotential in the ideal limit of infinite magnetic permeability.⁵ The geometry of such passive pole pieces is obtained from the same solution obtained with Eqs. (3.3) by considering the equipotential surfaces whose potentials $\pm\Phi_p$ satisfy the condition $\Phi_p \leq \Phi_{\min}$, where Φ_{\min} is the minimum of the magnitude of the ring potentials. By transforming these two equipotential surfaces into surfaces of infinite magnetic permeability, a pair of massive pole pieces is generated that entirely enclose the original plates.²

If $\Phi_p > \Phi_{\min}$, the equipotential surfaces $\pm\Phi_p$ do not completely enclose the plates. The transformation of the equipotential surfaces $\pm\Phi_p$ into surfaces of ferromagnetic material then results in hybrid pole pieces that leave a part of the filter region of the plates exposed. The potential shifts required on this exposed portion of the plates can be produced by embedding magnetic material in the plates, as for an active filter. An example of hybrid pole pieces is shown in Fig. 3, where Φ_p is equal to the potential $\Phi_0/2$ of the top plate inside the reference cylinder of radius r_i ; the filter structure consists of two rings designed to cancel the $n=2,4$ harmonics. Figure 3 also shows the boundaries of the regions of 10^{-4} and 10^{-5} field uniformity.

As previously stated, fabrication tolerances introduce odd order n and $m \neq 0$ harmonics, whose amplitudes are expected to be small compared to the amplitudes of the even-order harmonics generated by an ideal magnet. The components of the filter structure designed to cancel odd order n harmonics can be chosen to satisfy the condition

$$\delta\Phi_+(r) = +\delta\Phi_-(r). \quad (3.6)$$

Consider, for instance, a ring designed to cancel an $n=1$ harmonic. Following the same optimization procedure that leads to Eq. (3.5), the radial dimension of such a ring should be $2y_0/\pi$, which is about the same as the combined radial dimension of the three rings that cancel the $n=2,4,6$ harmonics. Therefore, the cancellation of this odd-order harmonic

can be achieved by modifying the potential of a group of rings designed to cancel even order harmonics. In general, the cancellation of the harmonics introduced by the tolerances may be achieved without introducing additional rings, and the shimming or adjustment of the distribution of $\delta\Phi_{\pm}$ in the filter elements is provided from the solution of the filter equations (2.2) with the right-hand side terms $(a_{m,n})_{1,2}$ being obtained from a measurement of the field of the assembled magnet. Hence, the design and shimming of a magnet are achieved with a unified approach.

As shown in the example of Fig. 3, the cancellation of the cylindrical harmonics provides a quasi-cylindrical region of field uniformity extending over the entire distance between the pole pieces. This property implies that the required geometrical precision inside the reference cylinder is much higher than that outside the cylinder. In particular, the precision inside the cylinder may have to be as small as a few microns to achieve uniformities of the order of 10^{-5} or higher.

Because of these precision requirements, a passive pole piece with a nonplanar surface inside the reference cylinder may be difficult to fabricate. Furthermore, a passive pole piece, being a rigid structure, requires additional components in order to shim the magnet. A hybrid pole piece designed for $\Phi_p = \Phi_0/2$ can more easily satisfy the precision requirements inside the reference cylinder and, because it contains active elements, has the flexibility needed for shimming. In addition, the hybrid structure is more compact. The advantage of a hybrid over a fully active pole piece is that it allows a significant amount of magnetic material to be eliminated, particularly in the external ring which usually requires the largest potential shift.

IV. CONCLUDING REMARKS

The analytic approach to the design of filter structures presented in this article provides a replacement for the iterative numerical methods that are conventionally used in the design of magnet pole pieces. Both the design and shimming of a magnet can be accomplished by following a unified, systematic procedure based on the expansion (2.1) and the filter equations (2.2). With a single computation, the designs for passive, active, and hybrid pole pieces are obtained. Hybrid pole pieces, which include both magnetic and ferromagnetic materials, may be easier to fabricate than either passive or active pole pieces, while having the flexibility required for a magnet's shimming.

Method based on the saturation approach law for monitoring the quality of texture in 3% Si-Fe

M. Birsan and J. A. Szpunar

Metallurgical Engineering, McGill University, 3450 University Street, Montréal PQ H3A 2A7, Canada

The magnetic saturation of a polycrystalline material is achieved as a result of rotation of the magnetization vector toward the direction of the applied magnetic field, against the magnetocrystalline energy. The magnetization rotation process in a grain-oriented material depends on the values of anisotropy constants, on the distribution of grain orientations, and on the direction of magnetization. Based on the magnetization rotation process, a simple instrument was devised and tested to monitor the differences of texture strength in grain-oriented 3% Si-Fe laminates. The simplicity and robustness of this instrument are remarkable and it can easily work on line. © 1996 American Institute of Physics. © 1996 American Institute of Physics. [S0021-8979(96)52708-2]

INTRODUCTION

When the magnetic-field strength gradually increases toward the value of the saturation field, the magnetization vector rotates toward the direction of the applied field against the magnetocrystalline energy. This is the saturation approach process, and it reflects the magnetic anisotropy of the material. The magnetic torque measured under these conditions provides information about the orientation of the magnetization vector with respect to the easy magnetization direction of the sample.

In grain-oriented 3% Si-Fe, the magnetization curve from saturation to remanence is primarily determined by the crystallographic texture. In this range of the hysteresis curve, the displacements of domain walls have already been completed and the magnetization occurs by rotation magnetization.

In a previous article,¹ a model-based method was developed to correlate texture and the coefficient representing the contribution of the magnetic anisotropy to the rotation process. It has been shown that, in a textured ferromagnetic material, the saturation approach law of the magnetization in the direction of the field is given by

$$I = I_s \left(1 - \frac{|\overline{C^2}|}{2I_s^2 H^2} \right), \quad (1)$$

where the information concerning the influence of texture on the magnetization rotation is fully contained in the $\overline{C^2}$ coefficient. Using the procedure of averaging a crystal property in a polycrystalline sample,² we calculated¹ the mean square value of the coefficient C over the crystal orientation distribution,

$$|\overline{C^2}| = K_1^2 \left(\frac{16}{105} - \frac{1}{9n_4\sqrt{\pi}} \frac{1}{9} F_4(\chi, \eta) + \frac{1}{13n_6\sqrt{\pi}} \frac{1}{275} F_6(\chi, \eta) + \frac{1}{17n_8\sqrt{\pi}} \frac{1}{4} F_8(\chi, \eta) \right),$$

where

$$F_8(\chi, \eta) = \frac{1}{\sqrt{2}} C_8^{11} \overline{P}_8^0(\chi) + C_8^{12} \overline{P}_8^2(\chi) \cos 2\eta$$

$$+ C_8^{13} \overline{P}_8^4(\chi) \cos 4\eta + C_8^{14} \overline{P}_8^6(\chi) \cos 6\eta + C_8^{15} \overline{P}_8^8(\chi) \cos 8\eta,$$

$$F_6(\chi, \eta) = \frac{1}{\sqrt{2}} C_6^{11} \overline{P}_6^0(\chi) + C_6^{12} \overline{P}_6^2(\chi) \cos 2\eta + C_6^{13} \overline{P}_6^4(\chi) \cos 4\eta + C_6^{14} \overline{P}_6^6(\chi) \cos 6\eta,$$

$$F_4(\chi, \eta) = \frac{1}{\sqrt{2}} C_4^{11} \overline{P}_4^0(\chi) + C_4^{12} \overline{P}_4^2(\chi) \cos 2\eta + C_4^{13} \overline{P}_4^4(\chi) \cos 4\eta. \quad (2)$$

In the above equation, χ and η are the spherical angular coordinates of the direction of the magnetization in the sample coordinate system, $P_l^n(\chi)$ are the normalized associated Legendre functions, and C_l^{nm} are the texture coefficients calculated from standard x-ray pole figure measurements. Thus, Eq. (1) illustrates that the magnetization rotation process in a grain-oriented material depends on the value of cubic anisotropy constant K_1 , on the distribution of grain orientations (texture), and on the direction in which the specimen is magnetized. This process was analytically described and experimentally tested.¹ Agreement between the experimental data and the predicted values was strong, demonstrating that the crystallographic texture controls the magnetization process from the knee of the magnetization curve to saturation. These theoretical findings were used to build an instrument evaluating the texture quality, and which can be implemented for on-line texture inspection.

TEXTURE QUALITY INSPECTION

In a constant magnetic field, strong enough to align the magnetic moments in each crystallite in one direction, the direction of the sample magnetization is determined by its crystallographic texture through the magnetic anisotropy energy. Based on this theoretical background, we devised a simple instrument which gives information about the quality of the texture by measuring the angle between the direction of magnetization in the sample and the direction of a fixed applied field. The measurement is indirect because, instead of the angular displacement of the magnetization vector, the

FIG. 1. Experimental setup for monitoring the quality of texture.

instrument measures the torque exerted by the sample magnetization on the external field produced by a permanent magnet.

The instrument is a modified torque magnetometer of the same type as the one described by Aldenkamp, Marks, and Zijlstra.³ The orientation of the magnetization vector relative to the magnetic field can be determined as follows: When a disk-shaped specimen is placed in a magnetic field H parallel to its plane, the torque exerted on the disk by the increasing field gradually increases with the strength of the field. The magnetization rotates from the sample easy magnetization direction toward the direction of the field, and the path followed by the magnetization I can be determined from the equilibrium condition

$$I H \sin(\eta_0 - \eta) = - \frac{\partial E_a}{\partial \eta}, \quad (3)$$

where η is the angle between an easy magnetization direction and the magnetization vector, η_0 is the angle between the same easy magnetization direction and the magnetic field, and E_a is the magnetic anisotropy energy. The transducer measured the torque exerted by the magnetic field on the sample magnetization.

This arrangement could be reversed: A magnet producing the horizontal field is fixed relative to the sample which is placed in front of the magnet with the normal direction (ND) perpendicular to the field. In this case, the magnetometer records the torque produced by the sample magnetization acting on the fixed permanent magnetic field. The electromagnet was removed and the new setup is illustrated in Fig. 1. A strong permanent Nd-Fe-B magnet ($H_c = 480 \times 10^3$ A/m = 6000 Oe) attached to the magnetometer rod magnetized the sample above the value of the magnetization knee. If the magnetic field is not oriented along the easy direction of magnetization, the magnetization direction in the sample does not coincide with the direction of the field due to the magnetocrystalline energy. For a magnetic field of constant direction and magnitude, strong enough to magnetize the

sample above the magnetization knee, the direction of magnetization depends only on the texture of the sample, as was previously illustrated.¹

The material used for analysis is a coarse grain-oriented metal sheet placed horizontally underneath the permanent magnet which is hung through the glass rod on the lower suspension of the torquemeter head. The material thickness is 9 mil (=0.21 mm) and, therefore, we assume that the overall magnetization is confined to the sheet plane, minimizing the magnetostatic energy caused by free magnetic poles on the sheet surfaces. The magnetic-field vector H and the magnetization vector I are, therefore, coplanar, i.e., the magnetization rotation occurs in the sheet plane.

The magnetic anisotropy of grain-oriented 3% Si-Fe materials is associated with a crystallographic $\{110\}\langle 001 \rangle$ texture. As has been demonstrated,¹ when the applied field lies between $\eta = 0^\circ$ and $\eta = 45^\circ$ directions of the sample, a higher value of the lag angle between the magnetization and magnetic field corresponds to a better orientation of the crystallite easy magnetization directions along the sample rolling direction. Since the torque measures the sine of the angle between the magnetization and the magnetic field, it provides information about the perfection of grain orientation in the sample.

The permanent magnet produces a constant magnetic field, which is a function of the distance between the permanent magnet and the sample plane. To obtain comparable information about the texture quality of different materials, the tests must be performed at constant magnetic field, which means a constant distance between the permanent magnet and the surface of the sample. The large dimensions of the metal sheet, practically infinite size in comparison with the dimensions of the permanent magnet, exclude the possibility of the free magnetic poles appearing inside the sample, so that the demagnetizing field can be considered zero.

The instrument was experimentally tested in the laboratory on two pieces of grain-oriented metal sheets of different texture quality. We call these two specimens OR-A (good quality) and OR-B (poor quality). The OR-A specimen has a smaller dispersion angle of the $\langle 001 \rangle$ directions around the rolling direction than specimen OR-B. The material texture is represented using the orientation distribution function (ODF). To illustrate the texture differences, Figs. 2(a) and 2(b) present the $\varphi_2 = 0^\circ$ section of the orientation distribution function (ODF) for the two samples.

The objective of the laboratory test was to identify the optimum position of the magnet relative to the sample rolling direction and to evaluate the sensitivity of the method. Starting from a position where the direction of the magnetic field coincides with the rolling direction (RD), the metal sheet was rotated 45° , and the signal proportional to the torque was recorded by the instrument in 2.5° steps. The results obtained for the two samples are shown in Fig. 3. The difference in torque value between the two specimens is significant when the permanent magnet is situated at approximately 12° from the rolling direction. For the two examples considered here, the difference in magnetic torque corresponds to approximately 1000 N m/m^3 .

The shape of these curves is less important for our pur-

FIG. 2. $\phi_2=0^\circ$ ODF sections for (a) sample OR-A and (b) sample OR-B.

poses; however, one has to emphasize that the curve shape does not reflect the sample symmetry, but it is a result of the interaction between the sample magnetization and the permanent magnet. To illustrate this, we deduce a qualitative expression for the torque obtained using the presented instrument.

If the magnetic field \mathbf{H} is oriented in a direction lying in the sheet plane, and with an angle η_0 to the sample easy magnetization direction, the magnetization direction in the sample plane is determined by the equilibrium condition (3), where the torque $L(\eta) = \partial E_a / \partial \eta$ is a function of the texture coefficients of the material.²

FIG. 3. Torque signal recorded from the two grain-oriented samples.

Let us assume that the relative permeability of the sample in the direction $(90^\circ, \eta)$ is $\mu(\eta)$. The problem of permeability variation with the angle from the easy magnetization direction of the sample is discussed elsewhere.^{4,5} Here, we consider^{6,7} that the permeability is described, to the first approximation, as a linear function of $F_4(\eta)$, defined in Eq. (2), and, as a result, one can write

$$\mu(\eta) \approx \mu_2 \cos 2\eta + \mu_4 \cos 4\eta, \quad (4)$$

where μ_2 and μ_4 are material constants.

The magnetization in direction $(90^\circ, \eta)$ is related to the component of the magnetic field in this direction through the relationship

$$I(\eta) = \mu(\eta) H(\eta_0) \cos(\eta_0 - \eta). \quad (5)$$

Substituting Eqs. (4) and (5) in Eq. (3), we obtain

$$\begin{aligned} L(\eta) &= \frac{1}{2} \mu(\eta) H^2(\eta_0) \sin 2(\eta_0 - \eta) \\ &\approx L_0 + L'_4 \cos 4\eta + L''_4 \sin 4\eta \\ &\quad + L'_6 \cos 6\eta + L''_6 \sin 6\eta + \dots, \end{aligned} \quad (6)$$

where the coefficients of the series are functions of η_0 , H , and texture coefficients. The presence of the sine functions in the above equation shows that the symmetry of the torque curve is not orthorhombic (sample symmetry). From this point of view, the instrument is not appropriate for obtaining texture information. What is important is that the experimental curves reflect the differences in texture between the two materials.

In the proposed industrial application of the instrument, the direction of the magnetic field created by the permanent magnet should be constant relative to the rolling direction, for example, at 12.5° where the difference in torque signal is maximum. The instrument must be calibrated using materials of known texture.

The simplicity and robustness of this instrument are remarkable. This instrument could be readily implemented to monitor the quality of the grain-oriented materials on line. When implemented on the processing line, the designed instrument would indicate the variation in the texture of the final product.

CONCLUSIONS

The approach to saturation law has offered us the theoretical background for obtaining information about the quality of material texture. A method to evaluate texture was devised and tested using a modified torquemeter. The variations in texture quality were easily detected. This method can be implemented on line and may be of practical importance to the grain-oriented steels industry.

Construction of novel magnets for generating astatic fields in x-ray topography

Tetsuo Nakajima

Photon Factory, National Laboratory for High Energy Physics, Oho 1-1, Tsukuba, Ibaraki 305, Japan

Masami Yoshizawa

Saitama Institute of Technology, Fusaiji, Okabe, Saitama 369-02, Japan

Superconducting (*S*-type) and normal-conducting (*N*-type) magnets, which can freely change the direction and strength of the fields, were constructed due to an incidental requirement concerning x-ray diffraction. Both magnets comprise three pairs of solenoids, the axes of which intersect orthogonally at the central point. Each pair of solenoids is independently excited by bipolar electric power sources. Alternating and direct current magnetic fields applied to an arbitrary direction $[h_1k_1l_1]$ in a single crystal can be varied to another direction $[h_2k_2l_2]$, parallel to an arbitrary curved surface. The components (H_x , H_y , and H_z) from each solenoid were simultaneously measured using three Hall elements. The prescribed magnetic field (H) was accurately synthesized by computer control of the electric power sources through the direction cosines, H_i/H ($i=x, y$, and z). The magnet was used to take synchrotron radiation x-ray topographs of α -Fe-3% Si in magnetic fields swept in the (110) plane from $[002]$ via $[222]$, $[110]$, $[222]$, and $[00\bar{2}]$ to $[002]$. In the *S* type, an inner metal Dewar having a transmittable part of an x-ray beam made of a confocal beryllium cylinder was installed in order to generate temperatures higher than 4.2 K. © 1996 American Institute of Physics. [S0021-8979(96)52808-7]

I. INTRODUCTION

In x-ray diffraction, samples set on a four-circle goniometer, used for determining the crystal structure, can be irradiated by the incident beam into an arbitrary direction $[hkl]$ of a crystal. However, the direction of the magnetic fields rigidly fastens onto either the pole direction or the axis of the solenoid. To make the magnetic field direction goniometrically controllable, two original types of the *S*- and *N*-type magnets were constructed, in which the direction of the magnetic fields generated by a set of three pairs of independent solenoids, regardless of the direction of the solenoid axes, can be goniometrically controlled by three bipolar electric-power sources. The axes of the three pairs of coils intersect orthogonally at the central point in both the *S* and *N* types. Differing from the usual type magnet, the direction of the fields are *unsettled*, i.e., *astatic*. Hence, alternating or direct current magnetic fields applied to a crystal can vary from one direction $[h_1k_1l_1]$ to another $[h_2k_2l_2]$ while remaining parallel to an arbitrary curved surface. A test measurement of the SR x-ray topography of α -Fe-3% Si is described.

II. INSTRUMENTATION

A. Three-channel gaussmeter

The components (H_x , H_y , and H_z) of the magnetic fields were simultaneously measured using a three-channel gaussmeter (series-9900 made by F. W. Bell Inc., USA). Knowledge of the components is essential for controlling the strength and direction of the magnetic fields. The direction cosines (H_i/H , $i=x, y$, and z) correspond to the Miller indices $[hkl]$ in a single crystal, respectively. [Here, H is equal to $(H_x^2 + H_y^2 + H_z^2)^{1/2}$]. An assembly of two Hall gen-

erators, in which two are the plate type with an active area of approximately $0.040''\phi$ and one is a cylinder type with an active area of approximately $0.020''\phi$, is used to measure H_x , H_y , and H_z .

Neglecting the resistive voltage, the coupling between coils, and the oscillations with current changes, the bipolar power supplies act as ac power sources. Therefore, a modified simple circuit as shown in Fig. 1 for three pairs of solenoids with three bipolar electric-power sources has been used.

Both astatic magnets were excited by three bipolar electric power sources. The rated output of power supplies were ± 16 V, ± 82 A and ± 43 V, ± 82 A for SPEC-88703 and SPEC-88704, respectively. Diodes (Toshiba 60JC15 or Nihon Inter 20M60) and rheostats (1 Ω , with a 60 amp current capacity) were attached as guard circuits against quenching of the superconducting coils. Variations of each component of the magnetic fields are controlled through a GPIB interface to a computer. The fields are increased or decreased by choosing a plus or minus current increment defined by the total current (164 amp) divided by 1000. Hence, the fields change by a stepwise cyclic pace of H_x , H_y , and H_z , closely paralleling the desired path. Adjusting the coincidence between the directions of the fields and the orientation of the Hall generators was carefully done.

B. Three axial split magnet

1. The *S*-type magnet

Figure 2 shows a cross-sectional view of the layout of the *S*-type magnet (A), together with the outer (B) and inner (C) Dewars. The coils, wound with single-strand NbTi, wire comprise a compound winding, and are identical in size. The

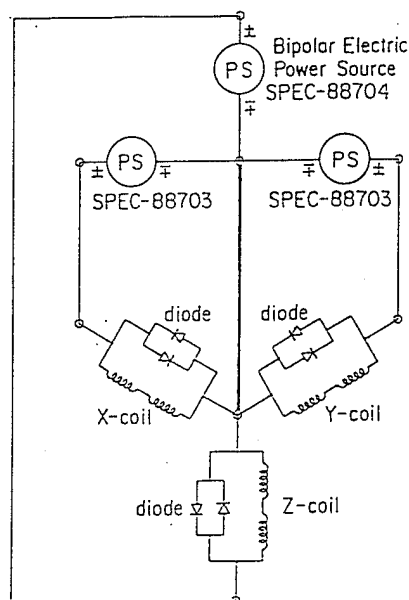

FIG. 1. Circuit of three pairs of X, Y, and Z coils and three bipolar electric-power sources.

coil constants lie between 0.01268 and 0.01259 T A^{-1} . The strength of the magnetic field at the central point is about 0.5 T with a homogeneity of 24% within a $10 \text{ mm}\phi$ spherical volume. Thus, the resultant maximum field is nearly equal to about 0.86 T , parallel to the $[111]$ direction at about 40 A . Photographs giving a general view of the S-type magnet and a bird's eye view of Dewar's top flange are shown in Figs. 3(a) and 3(b), respectively. The outer metal Dewar shown in Fig. 2 has four twofold x-ray transmission windows, which consist of two different sizes of beryllium plates: $80 \text{ mm}\phi$

FIG. 2. Cross-sectional view of the layout of the S-type magnet.

FIG. 3. Photographs of a general view of the S-type magnet (a) and a bird's eye view of Dewar's top flange (b).

$\times 0.5 \text{ mm}$ thick sealed by an indium-coated *helicoflex* metal O ring on the inside windows of liquid helium container, and $140 \text{ mm}\phi \times 1.2 \text{ mm}$ thick sealed by a neoprene O ring on the outside windows at room temperature. The aperture angle in each window is set to be $\pm 15.0^\circ$. The duration of operation with 16ℓ of liquid helium is about 15 h . The warning level is monitored by a liquid helium level meter.

The low part of the confocal walls of the inner Dewar (i) in Fig. 2 was made of two beryllium cylinders with a diameter of 30 and 20 mm and length of 30 mm which formed the vacuum jacket. The sample holder is connected to an accurate θ -rotation stage (ii) driven by a stepping motor (iii), which has an angular resolution of $1 \times 10^{-4} \text{ deg}$ per pulse, independently confirmed by encoder (iv). Generally, the full width at half maximum (FWHM) of the diffraction pattern gives $\pm \Delta q_{\parallel}$ parallel to the scattering vector \mathbf{q} , which expresses any fluctuation of the length in the periodicity and the FWHM from the rocking curve gives $\pm \Delta q_{\perp}$ perpendicular

FIG. 4. Topographs of (110) Laue spots of α -Fe-3% Si single crystal: (a) (110) at $H=0$ Oe, (b) 320 Oe \parallel [002], (c) 320 Oe \parallel [222], (d) 320 Oe \parallel [002].

lar to \mathbf{q} , which expresses any fluctuation of the direction in periodicity. Both quantities are complementary, which is important for gaining a better understanding of the crystal structure based on topographs.

2. N-type magnet (Ref. 1)

The three pairs of coils for the N-type magnet have three different sizes. The maximum fields are up to about 337 Oe

at 30 A for the smallest and medium coils and the same field at 60 A in the largest one. The maximum heat generations are about 165, 800, and 2400 W, respectively. Thus, in order to cool the coils, the maximum flow rates of water are 0.4, 2, and 4 ℓ per min, respectively. The field homogeneity of each coil is typically one part in 1×10^{-4} within a 10 mm ϕ spherical volume at the central point.

III. EXPERIMENTAL RESULTS AND REMARKS

White SR x-ray topographs of an α -Fe-3% Si single crystal in magnetic fields swept by the N-type magnet in (110) from [002] via [222], [110], [222], [002], to [002] were taken using SR x-ray beams of 6 mm \times 2 mm. To take topographs with $2\theta_B = 90^\circ$, SR x-ray beams were injected into the specimen of a thin plate parallel to (110) at an angle of 45° , which is the Bragg angle (θ_B). Magnetic fields were swept in the (110) plane through the above-mentioned path. These procedures are only feasible using this type of the magnet. Topographs were taken by using Ilford nuclear emulsion plates L4. The axis of easy magnetization in α -Fe-3% Si is in the [200] direction. Figures 4(b) and 4(d) show the magnetic domain structures nearly parallel to [002] and to [002], respectively. In Figs. 4(a) and 4(c), no clear geometrical pattern of the magnetic domain structure could be observed.

The astatic magnet is applicable not only to SR x-ray diffraction and solid state physics, but also as a novel insertion device for an SR light source. The insertion device would consist of several two-axis astatic magnets in series. The main characteristics resulting from using the astatic magnetic fields as insertion device are as follows: ease of (1) rapid production of polarized electromagnetic waves from linear polarization via elliptical polarization to circular polarizations by control of the power sources, (2) arbitrary rotation of the polarization plane in linear polarization, and (3) switching from left-circular light to right-circular light, and vice versa, in circular polarization.

Modeling and design of magnetic components require primary data on material hysteresis properties. In this article a flexible and highly automized system is described, which is suited for the characterization of the low frequency soft magnetic behavior (≈ 5 Hz–2 kHz) of ferromagnetic samples. The apparatus consists of a PC with the control program, a modular data acquisition/signal generation system, and a remotely controllable power amplifier to which the sample is connected. Integration of the secondary output voltage is performed digitally. The system operates in current control mode, and the user can select from a variety of adjustable excitation functions and even complex measurement procedures. It is possible to perform stationary or transient measurements of major and minor loops, initial magnetization and commutation curves, to do automatic demagnetization, and to output specific parameters which are necessary for sample characterization or model calibration. Amplitude selection and autoscaling of the measurement sensitivity can proceed within wide dynamic ranges. Sample, signal parameter, output, and characteristic data can be printed or plotted, edited, saved, reloaded, or changed in format. A number of different options for measurement and postprocessing are available. Instead of $B(H)$ also $M(H)$ or $\mu(H)$ curves or time signals can be displayed. Future software versions will also support the voltage control mode (which is already provided in the amplifier), and the measurement of the anhysteretic curve. A selection of example measurements obtained for two samples and with different types of excitation signals indicates the suitability of the system for various applications. © 1996 American Institute of Physics. [S0021-8979(96)52908-5]

I. INTRODUCTION

Modeling and design of magnetic components often require more information on the hysteresis properties than usually available from the suppliers. This holds in particular for applications when (apart from nonlinearity and loss) signal symmetry (minor loops) and transient response are of importance.¹ Experimental characterization of the complex hysteresis behavior of soft magnetic materials may be either rather tedious or it requires a very flexible tool.

Former approaches of programmable hysteresis loop tracers^{2–4} are often tailored to specific applications in that they either do not support core modeling, are restricted to a small frequency range, or (without reprogramming) to a few fixed test procedures and excitation signals.

In this article a hysteresis measurement system is described, which has been developed for the measurement of the low frequency response (≈ 5 Hz–2 kHz) of soft ferromagnetic samples to “arbitrary” periodic or transient signals. Also complex measurement functions can be performed. The apparatus is computer-automized, while the user is still given full control of all its functions at the same time. Characteristic hysteresis parameters necessary for sample characterization and model calibration can be extracted.

II. DESCRIPTION OF THE HARDWARE

The schematic diagram of the hysteresis loop system is shown in Fig. 1. It consists of mainly four components, which are an IBM compatible PC with the software for control and data evaluation, an external modular system with plug in boards for data acquisition and signal generation, the power amplifier to which the sample is connected, and the power supplies for the amplifier.

The sample may be either of toroidal or stripe shape (with known demagnetization factor). It must be provided with two appropriate windings (for primary current and secondary voltage) which are connected to the amplifier by four screw terminals.

Nearly all the functions of the power amplifier can be both controlled by the front panel or by PC (via the digital I/O port of the modular system). It can be operated either with current (ranges 0.25, 2.5, and 25 A) or voltage control (gains 1 or 4.5) with a maximum output voltage of ± 48 V. Input voltage for full range output current is ± 10 V. Offset can be fine-adjusted manually. Maximum bandwidth of the amplifier is 30 kHz. For the reduction of internal losses the supply voltage can be controlled from the PC with an 8-bit resolution. Two analog output voltage signals corresponding to the primary current and the secondary voltage of the sample are connected to the data acquisition system.

The modular data acquisition/signal generation system (MUSYCS/IMC) is internally synchronized; however, all its functions are programmed from the PC via a serial interface. The current and voltage signals are sampled with a maximum total rate of 1 MHz, converted with 12-bit resolution and stored in the local 4 MB-RAM before they are transferred to the PC for further processing. For frequencies below 100 Hz the horizontal resolution is limited to 2000 samples per signal period by the software (this is reduced at higher frequencies). Input ranges can be set from ± 50 mV up to ± 50 V. Acquisition is triggered by a pulse from the four-channel synthesizer board (± 10 V, 12-bit, common time base of maximum 1 MHz per channel with a depth of 8000 samples each) which at the same time starts generating the amplifier input signal. By means of an integrated programmable attenuator it is possible to use the full 12-bit

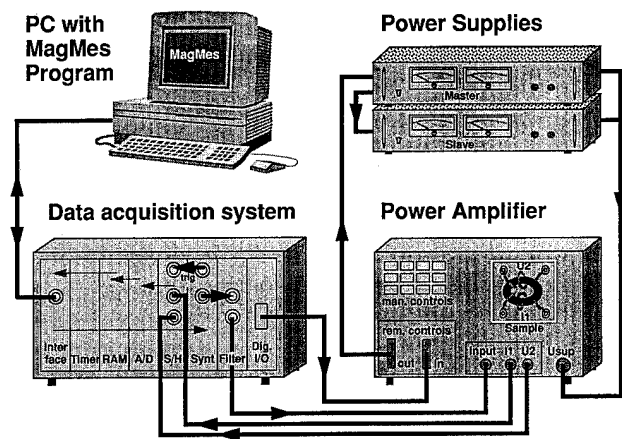

FIG. 1. Schematic diagram of the computer controlled hysteresis measurement system. The sample is provided with two windings which are connected to the power amplifier by screw terminals.

resolution with small amplitude signals. Before the output is transmitted to the amplifier it is first routed through a programmable low pass filter in order to reduce digital noise. Control of the amplifier modes and ranges is performed by a digital I/O board with 24 output channels.

III. DESCRIPTION OF THE SOFTWARE

The "MagMes" system software is a menu structured FRAME program using MUSYCS and FAMOS functions. It runs under MS-WINDOWS.

The measurement system is controlled from the main dialogue. It contains two curve windows which typically display the measured $I_1(t)$ and $U_2(t)$ time signals and the $B(H)$ hysteresis curve (the latter is obtained by digital integration!). Further, there are controls for triggering a new (autoscaled!) measurement and for on-line adjustment of signal amplitude and power supply voltage. Signal type, amplitude, and frequency as well as the sample name are also displayed. Other functions can be called by referring to the pull down menu bar on top of the dialogue window:

The functions of the "Sample Menue" allow to edit, print, save, and load those parameters of the device under test, which are necessary for calculation of secondary data or for correct demagnetization and excitation. Apart from the winding numbers and areas, the core geometry and demagnetization factor, the saturation field and the number of signal cycles necessary to reach a stationary magnetic state of the sample can be defined.

Likewise, there is a "Signal Menue," which allows to edit, store, and load signal parameters. There are different types of signals which can be selected: periodic signals (like sine, square, or triangle), nonperiodic (sine with linearly or exponentially varying amplitude, "arbitrary" steady signals composed of sine half-waves), and more complex procedures like the measurement of commutation and anhysteretic curves (will be implemented in the next version). For each of

FIG. 2. 1 kHz initial magnetization curve and Rayleigh loop (1 A/m) of a T38 ferrite ringcore. Dependent on the type of measurement characteristic values of fields, inductions, permeabilities, and power loss of the curve are calculated and can be printed out.

FIG. 3. 5 Hz commutation curve of an Ultraperm F80 ringcore. In an automatic procedure every point of the curve is measured at least with the number of cycles necessary to reach the stationary state of the core.

FIG. 4. Response of an Ultraperm F80 ringcore to a series of unipolar 50 Hz sine pulses cut at 135° (test for residual current transformers).

FIG. 5. Minor loops located at any point within the major loop can be constructed by "arbitrary" signals composed of sine half-waves.

the signal types there is a "Parameter Menu," in which amplitude, frequency, offset, duty factor, and other parameters can be defined. For sine-type signals in particular, one of the subtypes "standard, half-bridge, full bridge, phase control or pulse" can be chosen. The possibility of outputting just a few signal cycles enables the generation of high field amplitudes without causing thermal problems. The signal waveform data are calculated and transmitted to the synthesizer immediately before the measurement.

In the "Measurement Menu" it is possible to select options for measurement, data evaluation, curve display, and data output. Further, a set of numerical results for the current curve can be displayed. Optionally, automatic sample demagnetization voltage- or B -offset compensation, and input signal filtering can be performed. The kind and format of the curve display [$B(H)$ vs $M(H)$ or $\mu(H)$; $H(t)$ and $B(t)$ vs $I(t)$ and $U(t)$] as well as the file format for data output (ASCII or adapted to the MagCAD preprocessor used for model calibration) are selectable. In other menus it is possible to load, print, or plot data.

Up to now, MagMes only supports current control, though the amplifier can work both with I and U control.

IV. EXAMPLE MEASUREMENTS

The following figures show only some examples of measurements which are possible with MagMes. In Fig. 2 the

initial magnetization curve and Rayleigh loop measured on a demagnetized T38 ferrite ringcore with two cycles of a 1 kHz standard sine signal are displayed together with the automatically calculated numerical results. Apart from amplitude permeability and other characteristic hysteresis parameters also some values of the differential permeability at different locations on the curve are given.

Figure 3 shows the results of a low frequency commutation curve measurement performed on a highly permeable strip wound core. The individual points on the curve are determined with selectable resolution in a stepwise automatic procedure.

Figures 4 and 5 show hysteresis curves resulting for special types of the excitation waveform: A 135° cut unipolar sine signal is used for tests on pulse sensitive residual current circuit breakers. Due to the decrease of remanence during $H=0$ larger values of B (and thus of the output voltage) are obtained! With a composed signal like in Fig. 5 the properties of minor loops located anywhere within the major loop are accessible.

Alternating current-excited magnetoresistive sensor

P. Ripka^{a)}

Czech Technical University, Faculty of Electrical Engineering, Department of Measurement,
166 27 Praha 6, Czech Republic

Thin-film anisotropic magnetoresistors are superior to semiconductor magnetic field sensors. ac excitation of the sensor bridge reduced the noise level to 10 nT *p-p*. The offset reduction and sensor characteristic stabilization was achieved by periodical flipping by means of 100 mA/100 μ s current pulses into a 400 turns coil wound across the sensor perpendicular to the sensitive axis. The use of the flipping mechanism can significantly improve the performance of the permalloy anisotropic magnetoresistors: long-term offset stability of 10 nT, hysteresis below 100 ppm FS and 5 nT *p-p* noise can be achieved with low-power sensor electronic circuits. The array of eight magnetoresistors was used in a contactless dc current meter. A sensitivity of 0.1 mA and high geometrical selectivity was obtained. © 1996 American Institute of Physics. [S0021-8979(96)53008-7]

Commerically available thin-film anisotropic magnetoresistor bridges such as Philips KMZ or Planartechnik KMY are superior to semiconductor magnetic field sensors. Their bridge structure is schematically shown in Fig. 1; individual resistors have a meander shape to increase the effective length. The "barber pole" structure made of aluminum strips on the permalloy surface causes the deflection of the current direction by 45° from the field sensitive axis (*y*), and thus linearizes the sensor characteristics.¹ The sensors should be premagnetized in perpendicular (*x*) direction along the strip length. Afterward the *x*-direction field should be kept low to avoid possible distortion of the characteristics.

Sensor sensitivity can be further increased: Veith *et al.*² reached values of more than 100 mV/V/mT by 2.5-mm-long sensor, Smith *et al.*³ reported sensitivity of 400 mV/V/mT using thin-film flux concentrators. The sensors may have resolutions of 10 nT which is sufficient for compass applications, contactless current sensing, and proximity sensing applications. A single magnetoresistor compass was described by Paperno and Kaplan.⁴

The measurements reported in the present article were performed on a Philips KMZ10A1 sensor. The sensor sensitivity for 5 V dc bridge supply was 70 V/T; the magnetometer output fluctuations are thus caused not only by fluctuations of the magnetoresistance, but also by input amplifier 1/*f* noise at ultralow frequencies and even by bridge thermal noise.⁵ Significant improvement can be observed when the bridge is excited by an ac signal. Using 10 V *p-p* square-wave excitation and lock-in amplifier for the signal processing, we observed no change in the sensitivity for excitation frequencies from the 150 Hz to 15 kHz. Figure 2(a) shows how the low-frequency sensor noise was reduced: the power spectral density at 1 Hz was 3.6 and 1/6 nT/ $\sqrt{\text{Hz}}$ for dc and squarewave supply, respectively. The instrumentation noise level was below 0.1 nT/ $\sqrt{\text{Hz}}$ (measured for the excitation switched off). Figure 2(b) is the time plot for the ac supplied sensor output: the *p-p* noise is 10 nT.

The main disadvantage of the permalloy magnetoresistors is the danger of distortion of their characteristics by a field in perpendicular (*x*) direction. Figure 3 shows the sensor characteristic for the measured field declined by 10° from the *y* axis. The field component in *x* direction causes the change of the magnetization in easy direction so that for higher field values, the characteristic changes its polarity.

The mentioned flipping effect can be used for stabilization of the sensor characteristic. The permanent magnetization in the easy direction was changed by current impulses into the 5-mm-long, 6-mm-i.d. coil of 400 turns wound across the sensor (Fig. 1). Figure 4 shows the sensor characteristics for changing the polarity and amplitude of the flipping pulses: 100 mA current impulses which create a maximum field of about 4 kA/m in the coil center guarantee stable operation.

The electronic circuit which was developed generates flipping pulses of 100 μ s duration and 800 μ s repetition rate with successively altering polarity. The sensor output is read by a gated integrator for 100 μ s in between each of the flipping pulses. The resulting characteristic is shown in Fig. 5. Sensor modulation reduces the offset by one order of magnitude to below 1 mT, hysteresis to below 100 ppm FS and long-term offset variations to below 10 nT; the temperature coefficient of the sensitivity (10^{-3} K^{-1}) remained unchanged.

FIG. 1. Permalloy magnetoresistive sensor. The bridge consists of four resistors with "barber pole" structure. The sensor measures magnetic field in the "*y*" direction.

FIG. 7. Output noise of the current meter from Fig. 6: zero output in shielding (upper trace) and response to 2 mA current step (lower trace).

array axis causes a maximum error of 20 mA depending on the angular position. The Earth's field caused a maximum error of 15 mA. Most of this error is due to the sensor array imbalance caused by tolerances of individual sensor sensi-

tivities, which were from 1.08 to 1.29 mV/A. Further improvement is expected to be achieved by adjusting the individual sensor sensitivities and by the use of flipping for the stabilization. The current resolution achieved is shown in Fig. 7: The sensor's own noise is equivalent to 0.1 mA *p-p*. This makes the sensor worth further development, as the commercially available dc current clamps using Hall sensors in the air gap have only 10 mA resolution.

Magnetic field distribution caused by a notebook computer and its source searching

T. Doi, S. Hayano, and Y. Saito

College of Engineering, Hosei University, Koganei, Tokyo 184, Japan

Previously, we have proposed a method of solution for the inverse problems, and successfully applied it to the biomagnetic fields. In the present article, we apply our inverse approach to the leakage magnetic field source searching for the notebook computers. As a result, it is found that our inverse approach is quite effective in searching for the leakage magnetic field source. The validity of our solutions is carefully examined by comparing the measured and calculated magnetic field distributions. © 1996 American Institute of Physics. [S0021-8979(96)53108-4]

In order to prevent the misoperation and mutual action among the electronic devices, a magnetic shielding is one of the key techniques in the electromagnetic compatibility (EMC) field. Searching for the magnetic field source from locally measured magnetic fields is reduced into the solution of an inverse problem. Inverse problems are classified into two major categories, i.e., one is the inverse parameter problem¹ and the other is the inverse source problem.²⁻⁴ In order to shield the leakage electromagnetic field from the electronic devices effectively, it is essential to solve the inverse field source problem.

Previously, we have proposed the sampled pattern matching method as a method of solution for the inverse problems, and we have applied it to the biomagnetic fields as well as conventional nondestructive testing problems.¹⁻⁴

In the present article, we measure the magnetic field above the keyboard of a notebook computer as well as a typical example of electronic devices. And we apply our inverse approach to the leakage magnetic field source searching of the notebook computers.

Most of the inverse problem in the electromagnetic fields reduces to solving for a following governing equation

$$\mathbf{X}_p = \int_v G \mathbf{Y}_s dV, \quad (1)$$

where \mathbf{X}_p , \mathbf{Y}_s , G , and V are the known field vector, unknown source vector, Green's function or its space derivative, and volume containing the unknown source vector, respectively.

In the sampled pattern matching (SPM) method, we assume that the magnitude of a field source at each position can be represented by the space occupying rate of unit source. This means that the governing Eq. (1) is assumed to be modified into

$$\mathbf{X}_p^{[N]} = \int_p G^{[N]} \delta \mathbf{P}, \quad (2)$$

where superscript $[N]$ refers to the normalized quantities. Also, δ and P are the vector delta function representing the source vector \mathbf{Y}_s and $(|G|/|\mathbf{X}_p|)V$, respectively.

Physically, this transformation corresponds to the pulse width modulation (PWM) technique in power electronic engineering. Representation of the space occupying rate of unit source is one of the key ideas of the sampled pattern matching method.

Discretizing Eq. (2), we have

$$\mathbf{X}_p^{[N]} = \sum_{i=1}^m \Delta P_i \mathbf{G}_i^{[N]} = D \mathbf{P} \quad (3a)$$

$$\begin{bmatrix} \Delta X_{p1} \\ \Delta X_{p2} \\ \vdots \\ \Delta X_{pn} \end{bmatrix} = \begin{bmatrix} G_{11} & G_{12} & \cdots & \cdots & G_{m1} \\ G_{21} & G_{22} & \cdots & \cdots & G_{m2} \\ \vdots & \vdots & \ddots & \ddots & \vdots \\ G_{n1} & G_{n2} & \cdots & \cdots & G_{nm} \end{bmatrix} \begin{bmatrix} \Delta P_1 \\ \Delta P_2 \\ \vdots \\ \vdots \\ \Delta P_m \end{bmatrix}, \quad (3b)$$

where m denotes a number of subdivisions of the field source existing space. Denoting n as a number of field measured points (i.e., the order of vector $\Delta \mathbf{X}_p$), D becomes an n by m rectangular system matrix composed by the column vectors $\mathbf{G}_i^{[N]} (i=1,2,\dots,m)$, and \mathbf{P} is a m th order PWM field source vector whose element is $\Delta P_i (i=1,2,\dots,m)$.

In order to evaluate the vector \mathbf{P} in a least-squares sense, multiplication of D^T to both sides of Eq. (3a) yields

$$D^T \Delta \mathbf{X}_p^{[N]} = D^T D \mathbf{P} \quad (4)$$

or

$$\mathbf{P} = |D^T D|^{-1} D^T \Delta \mathbf{X}_p^{[N]}. \quad (5)$$

From Eq. (5), it seems able to evaluate the solution vector \mathbf{P} . But, this is practically difficult, because the column vectors $\mathbf{G}_i^{[N]} (i=1,2,\dots,m)$ constituting the system matrix D are not linear independent. In other words, the elements of matrix D have been obtained by discretizing the same continuous function G , so that the matrix $D^T D$ becomes a singular matrix. Thus, it is difficult to evaluate the vector \mathbf{P} by means of the conventional least-squares fit.

Consideration of the matrix $D^T D$ in (4) reveals that the diagonal elements take 1 but the other elements are always less than 1 because each of the column vectors $\mathbf{G}_i^{[N]} (i=1,2,\dots,m)$ in D is normalized. Thereby, the matrix $D^T D$ may be regarded a unit matrix with order m . This assumption means that Eq. (4) yields an approximate solution of \mathbf{P} , which coincides with those of a factor analysis. Further consideration of Eq. (4) suggests that the elements in (4) take values between -1 and 1 . Namely, the elements $\Delta P_i (i=1,2,\dots,m)$ in the vector \mathbf{P} are

$$\Delta P_i = \mathbf{X}_p^T \cdot \mathbf{G}_i / [\|\mathbf{X}_p\| \|\mathbf{G}_i\|], \quad i=1,2,\dots,m, \quad (6)$$

where the elements $\Delta P_i (i=1,2,\dots,m)$ of \mathbf{P} are called the *pattern matching figures*.

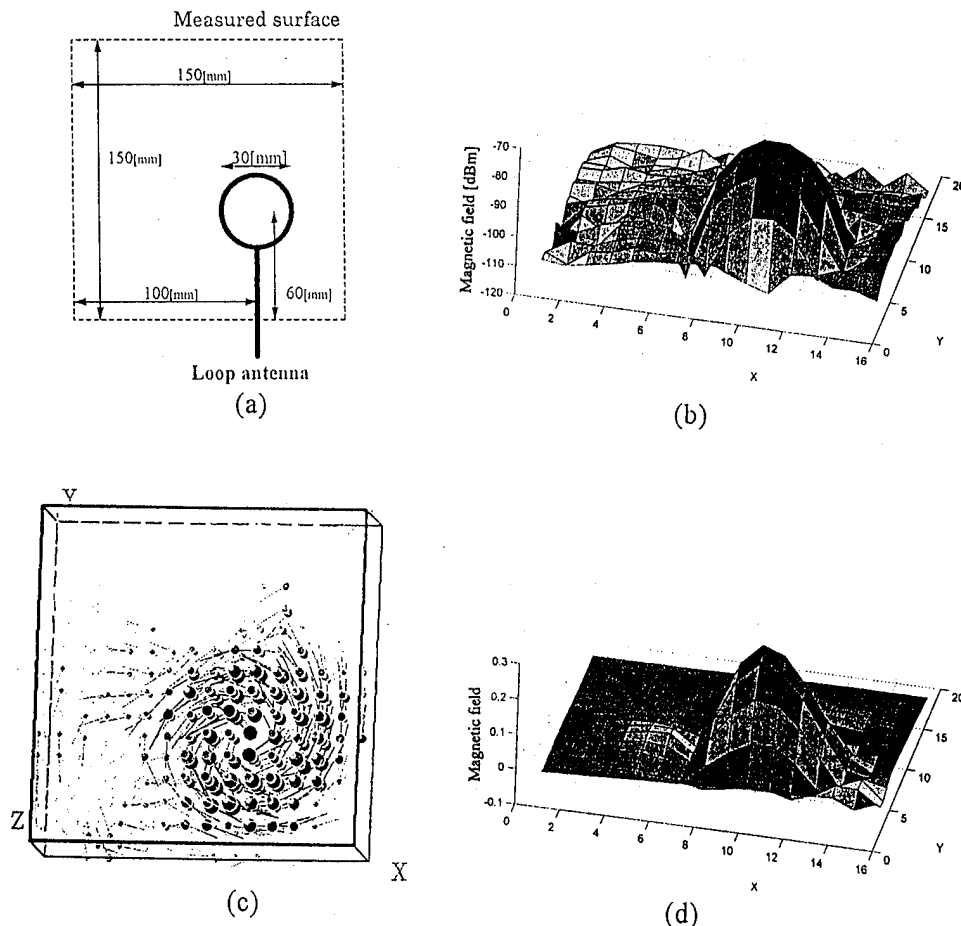

FIG. 1. An experimental result of the field source searching. (a) Schematic diagram of a loop antenna, (b) measured magnetic field distribution above the loop antenna, (c) estimated current distribution, and (d) reproduced magnetic field distribution by the currents in (c).

Since we have to decide the existence of vector delta function δ in (2) by the least-squares sense, the SPM method assumes that only one element taking the maximum pattern matching figure in Eq. (6) has a unit vector delta function. If the ΔP_h takes the maximum, then this point h is the *first pilot point* and its associated pattern vector \mathbf{G}_h is called the *first pilot pattern*.

The second pilot point is decided as the maximum element of

$$\Delta P_{hi} = \mathbf{X}_p^T \cdot (\mathbf{G}_h + \mathbf{G}_i) / [\|\mathbf{X}_p\| \|\mathbf{G}_h + \mathbf{G}_i\|],$$

$$i = 1, 2, \dots, m; i \neq h. \quad (7)$$

The similar processes of Eqs. (6) and (7) are continued until the peak value of the pattern matching figure is obtained. Finally, the field source \mathbf{Y}_s is transformed into the PWM field source pattern \mathbf{P} .

As shown above, one of the merits of the SPM method is that the SPM method gives a most dominant solution against a locally measured field pattern. For further details of the SPM method, see Refs. 1–4.

One of the problems of the field source searching is the validity of the solutions. In order to check the validity of solutions, a simple experimental example demonstrates the validity of the SPM method.

First, we measured the magnetic field having 75 MHz frequency above the loop antenna. Figures 1(a) and 1(b) show the schematic field distribution, respectively. The magnetic field above the loop antenna was measured with the spectrum analyzer. The 75 MHz current flows in the loop antenna. The magnetic fields at 256 (16×16) equispaced locations above the loop antenna were measured. Second, we applied the SPM method to this magnetic field. Figures 1(c) and 1(d) show the obtained current distribution from the locally measured magnetic field in Fig. 1(b) and the reproduced magnetic field distribution calculated from the currents in Fig. 1(c), respectively.

Obviously, the results in Fig. 1 suggest that the SPM method is capable of estimating the global magnetic field source distribution. Thus, the SPM method is a useful solution strategy for the leakage magnetic field source searching from the electronic devices.

We measure the leakage magnetic fields for the two types of notebook computers. One is operating at 75 MHz, and the other is operating at 100 MHz CPU frequency. Both the computers equipped the INTEL DX4 CPU.

The magnetic fields above the keyboards were measured with a spectrum analyzer under the full CPU condition.

(b)

(c)

FIG. 2. The leakage magnetic field source distribution searching of the notebook computer operating at 75 MHz CPU frequency. (a) The measured magnetic field distribution, (b) the estimated current distribution, and (c) the reproduced magnetic field distribution calculated by the currents in (b).

Figure 2(a) shows the measured magnetic field distribution having 75 MHz. Figures 2(b) and 2(c) show the estimated current distribution and the reproduced magnetic field distribution calculated by the currents in Fig. 2(b), respectively. The results in Fig. 2 suggest that the magnetic field source measured above the keyboard is roughly classified into two parts; one is the CPU and the other is the power supplier. Thus, the magnetic shielding should be carried out mainly to these two parts.

Figure 3(a) shows the measured magnetic field distribution having 100 MHz. Figures 3(b) and 3(c) show the estimated current distribution and the reproduced magnetic field distribution calculated by the currents in Fig. 3(b), respectively.

The results in Fig. 3 suggest that the magnetic field source measured above the keyboard is mainly caused by two parts: one is the power supplier and the other is the

signal flowing line to the display. Thus, the magnetic shielding of this computer should be carried out mainly to the power supplier and the line connecting from the CPU to the display.

In the present article, the validity of our inverse solution method has been carefully checked by means of the simple loop antenna. Further, it has shown that the different parts become the leakage magnetic field source depending on the circuit structure, and the common leakage magnetic field source of the two types of computers is the power supplier. This means that the magnetic shielding of any notebook computers should be carried out to the power supplier.

Highly sensitive magneto-optic transverse Kerr effect measurement system for the detection of perpendicular anisotropy and magnetic phases in thin films

J. A. Corrales, M. Rivas, J. F.-Calleja, I. Iglesias, and M. C. Contreras
Departamento de Física, Universidad de Oviedo, 33007 Oviedo, Spain

Transverse biased initial susceptibility (TBIS) measurements were made using a magneto-optical Kerr effect system on samples that exhibited an in-plane and a perpendicular anisotropy. A change in the slope of both the inverse transverse susceptibility and the hysteresis loop is observed at a certain value of the applied in-plane field H_s . At values of the applied field higher than H_s , the magnetization lies in the plane of the film; at values lower than H_s , an out-of-plane component appears. By performing TBIS measurements we can also detect different micromagnetic phases magnetically uncoupled with different values of the anisotropy field. The occurrence of a downwards curvature in the inverse susceptibility when the dc field is applied along the hard axis together with the multiple minima when the dc field is applied along the easy axis can be explained by the existence of weakly coupled micromagnetic phases. © 1996 American Institute of Physics. [S0021-8979(96)53208-7]

INTRODUCTION

Reflection magneto-optical effects are useful for obtaining information about the magnetization process that occurs on the sample surface.^{1,2} In the case of thin films thinner than 1000 Å in which there is no appreciable variation of the magnetic structure through the thickness, the magneto-optical effects provide complete information.

Magnetic films often show magnetic uniaxial anisotropy. The origin of such an anisotropy depends on the physical structure of the sample and in some cases it is a source of controversy, because there are several factors that can influence it simultaneously (magnetostriction, stresses, inhomogeneities, etc.).

It is experimentally observed that such a uniaxial behavior is not uniform all over the sample. There are macroscopical anisotropy fluctuations, that intuitively would correspond to macroscopically uniaxial regions of the sample for which the magnitude as well as the easy direction of the anisotropy changes from one region to the other. This long-range fluctuation is known as "skew" and can be studied from the transverse susceptibility.^{3,4}

Also, in polycrystalline and amorphous soft thin films the direction of local magnetization fluctuates from place to place. This short-range dispersion is caused by microscopical local anisotropy mainly due to structural and composition inhomogeneities and is known as "ripple." This ripple is predicted by the micromagnetic theories and observed experimentally by Lorentz microscopy.⁵ In the case of polycrystalline films this would correspond to the fact of being constituted by crystallites whose size is about a few hundreds of Å and in the case of amorphous films to the presence of slight local variations in the composition, in regions whose size goes from tens to hundreds of Å. The magnitude of the ripple can be studied from the transverse susceptibility.³

In conclusion, to understand the relationship between the physical structure and the magnetic properties of thin films it is very useful to use an experimental system that provides as

much information as possible about the processes that take place in real films.

PRINCIPLES OF THE EXPERIMENTAL TECHNIQUE

In a first-order approximation, the transverse Kerr effect consists of a small change in the reflectivity of p -polarized light proportional to the part of the magnetization that runs on the plane of the sample and perpendicular to the plane of the incident light. So any change of this component of the magnetization induces a proportional change in the intensity of the reflected light that can be detected by a photodiode with a linear response.

Transverse susceptibility is measured by applying two magnetic fields in the plane of the film: a dc bias field H_{dc} parallel to the plane of incidence of light from $10 H_k$ (to ensure saturation) to 0 and a sinusoidal field h_{ac} of small amplitude perpendicular to H_{dc} . The modulated Kerr signal is proportional to the component of the magnetization parallel to h_{ac} , δM . For the signal to be proportional to the initial susceptibility the amplitude of h_{ac} must be chosen small enough to ensure that we are working in the Rayleigh region of the sample, where the magnetization process is reversible and linear. In that case the variation of δM follows a sinusoidal law of the same frequency as h_{ac} . Typically we have $h_{ac} \approx 1\% H_k$. The working frequency was chosen to be different from that typical of electrical noise and its harmonics, in our case 127 Hz.

The light source was a halogen lamp (12 V, 50 W). The diameter of the spot on the sample was 3 mm.

The measured Kerr signal U is proportional to the transverse susceptibility: $U = k\chi_t$, with k a proportionality constant.

For the quantitative evaluation of the microscopic local anisotropy fluctuations, the dynamic differential susceptibility measurement proposed by Hoffmann is used.³ The inverse of the Kerr signal obtained experimentally is expressed as

$$U^{-1}(\beta) = k(\beta) \frac{H_k}{M_s} [(h \pm 1) + b(h \pm 1)^{-1/4} + c(h \pm 1)^{-1}], \quad (1)$$

where the plus sign corresponds to $\beta=0$ (dc bias field applied along the easy axis) and the minus sign to $\beta=\pi/2$ (dc bias field applied along the hard axis) and $h=H_{dc}/H_k$. The first term in Eq. (1) corresponds to the coherent rotation process (Stoner–Wohlfarth model), the second describes the contribution of the ripple related to short-range fluctuations of the magnetization, and the third term is the “skew” term caused by long-range fluctuations of the magnetic anisotropy.

These coefficients are given by³

$$b = \left(\frac{1}{4\pi\sqrt{2}} \right) S^2 M_s \sqrt{t/(AK_u)^{5/4}}, \quad (2)$$

$$c = 3\langle\theta^2\rangle \quad (3)$$

with $\langle\theta^2\rangle$ the mean square value of the skew angle.

Here, M_s , t , A , and K_u are the saturation magnetization, film thickness, exchange constant, and uniaxial magnetic anisotropy of the films, respectively. S is called the structure constant, which corresponds to the magnitude of short-period local anisotropy fluctuations.

All the films under study in this work were deposited by sputtering. All of them present an in-plane uniaxial anisotropy.

EXPERIMENTAL RESULTS

In certain alloys in which different magnetic phases may appear it is not certain that Hoffmann’s model for transverse susceptibility can be successfully applied. In other cases, the occurrence of a perpendicular component of the magnetization may also provoke the failure of the theory.

However, we can still use the magneto-optical Kerr effect (MOKE) to measure the transverse bias initial susceptibility (TBIS). It is noteworthy that the TBIS measurement is more sensitive than the measurement of the hysteresis loop: The easy axis and the anisotropy field can be determined

FIG. 1. $\chi^{-1}(\pi/2)$ vs h curves. Squares correspond to the experimental data; the solid line corresponds to the theoretically predicted curve with $b=0.06$ and $c=0$; the dashed line corresponds to the prediction from the coherent rotation model. The dotted line is a guide for the eye.

very precisely and moreover short- and long-range magnetization fluctuations can be distinguished and quantified.

Figure 1 shows the behavior of the inverse of the transverse susceptibility of a film that obeys the theory proposed by Hoffmann with negligible skew.⁶ In Fig. 2 we report the inverse of the transverse susceptibility for a film of Ni_{91}Y_9 that shows a gradient in composition across the sample area. Figures 3 and 4 correspond to two different zones of the same sample named A and B.

This behavior may be phenomenologically justified by a model in which the basic hypothesis is the existence of micromagnetically ordered regions isolated in a nonmagnetic matrix. Each region must have an easy direction of the magnetization and an anisotropy constant K_R . The spatial distribution of the easy directions is aleatory, all directions are equally probable, and there is no appreciable magnetic interaction among regions, so the global behavior of the transverse susceptibility of the sample may be analyzed from the individual contributions of each ordered region. In such a case the film would present an isotropic behavior, existing a linear relation between χ_i^{-1} and bias field H for H high enough (strictly for $H \rightarrow \infty$) and a maximum in the susceptibility for a value of H close to $H_{KR} = 2K_R/M_{sR}$ (M_{sR} being

FIG. 3. Experimental $\chi_{i,\beta}^{-1}$ vs H and linear extrapolations for the more isotropic region of the film Ni_{91}Y_9 . Circles represent $\beta=\pi/2$ and asterisks $\beta=0$.

FIG. 4. Experimental $\chi_{t,\beta}^{-1}$ vs H and linear extrapolations for the more anisotropic region of the film Ni_{91}Y_9 . Circles represent $\beta = \pi/2$ and asterisks $\beta = 0$.

the saturation magnetization of each micromagnetic region). This is due to the contribution to total susceptibility measured in any direction of the region in which the easy axis is perpendicular to the applied field H .

Real films are not always isotropic but present an anisotropic behavior that must be associated to a macroscopic anisotropy in each region induced by the fabrication process.

In Fig. 2 both $\chi_{t\pi/2}^{-1}$ and χ_{t0}^{-1} vs H curves show a minimum at different values of the bias field. The occurrence of the downwards curvature of χ_{t0}^{-1} in the range of low magnetic fields, together with the multiple minima in $\chi_{t\pi/2}^{-1}$ (regions A and B) can be explained by two micromagnetic phases weakly coupled. The two regions show two different values of H_k . These values are $H_k = 45.9$ Oe corresponding to an anisotropic region (Fig. 4) and $H_k = 6.9$ Oe for a more isotropic one (Fig. 3); the latter shows large magnetization dispersion, i.e., linear extrapolations asymmetrically cut the abscissa and both χ_{t0}^{-1} and $\chi_{t\pi/2}^{-1}$ show a minimum at nearly the same value of the bias field.

The occurrence of a uniaxial anisotropy whose easy axis is normal to the plane of the film is a fact often observed in magnetically ordered thin films. Above a certain critical value of the thickness⁷ and depending on the existence of stresses, magnetostriction, etc., magnetic films may present a domain structure with stripe domains in which the local magnetization has components of alternating sign normal to the plane of the film in addition to in-plane component.

Kerr magnetometers have been suggested as a good substitute for conventional magnetometers for measuring perpendicular anisotropy.^{2,8,9} TBIS measurements can be used as an alternative technique, as we will show.

Let us describe in a phenomenological way the influence of a perpendicular component of magnetization on the behavior of transverse susceptibility.

In these cases characteristic loops present a change in the slope for $H = H_s$. Figure 5 represents the inverse of the susceptibility versus the bias field for a film with perpendicular anisotropy and the associated hysteresis loop. Here we can see that at high values of dc bias field the magnetization is kept in the plane until the field is reduced below the saturation field, H_s . From this we may see that H_s can be esti-

FIG. 5. χ^{-1} vs H for a film with perpendicular anisotropy. The inset shows the hysteresis loop.

mated from the change in the slope of this representation as well as from the hysteresis loop with the important advantage that the TBIS measurement is much more sensitive than the measurement from the loop.

This behavior can be explained by the combination of two effects: On one side, the decrease of the magnitude of the magnetization in-plane component, as H decreases below the saturation field, H_s . H_s corresponds to the value of H above which the magnetization lies in the plane of the film and so the existence of the stripe domains and related phenomena disappear. On the other hand the effect of the anisotropy related to the direction of the stripe domain structures characterized by an out-of-plane component of the local magnetization must increase when H is diminished below H_s . Both effects contribute to the change in the slope of $\chi_{t\beta}^{-1}$ for $H = H_s$ and are difficult to separate *a priori*.

To summarize, TBIS measurements by MOKE can be used to detect different amorphous micromagnetic phases in a film allowing us to measure the anisotropy field of each separately. In the case of the existence of perpendicular anisotropy this technique can be used as an alternative technique to estimate a value of the perpendicular anisotropy field.

First-order magnetic phase transition in $(\text{Er}, \text{Tb})\text{M}_2 (\text{M}=\text{Co}, \text{Ni})$ (abstract)

A. Y. Takeuchi, F. Garcia, and S. F. da Cunha

Centro Brasileiro de Pesquisas Físicas-CBPF/CNPq, r. Dr. Xavier Sigaud 150, CEP-22290-Rio de Janeiro, RJ-Brazil

The rare-earth intermetallic compounds RCo_2 , cubic Laves phases, are very suitable to study the magnetism of the $3d$. Depending on the R magnetism we have an induced moment for the Co. For $\text{R}=\text{Dy}$, Ho , or Er the magnetic transition is of first order, whereas for Gd and Tb it is of second order. This behavior has been observed in this work by electrical resistivity and dc magnetization measurements in function of concentration in the system $(\text{Er}_{1-x}\text{Tb}_x)\text{Co}_2$ where the internal field of the nearest R neighbors can induce the Co moment. Magnetization measurements of field cooling (FC) and zero field cooling (ZFC) samples are different for $T < T_c$. This difference collapses for higher applied magnetic fields. The minimum¹ for T just above T_c in ρ vs T curves disappears for $x=0.2$ with the onset of the second-order transition up to $x=1.0$. This minimum can result from the conduction electrons scattering on the spin fluctuations, enhanced by the $4f$ moments and the scattering by phonons. The idea of the metamagnetism of Co moments in the origin of this minimum is discarded. From our results we can conclude that a small amount of Tb in ErCo_2 changes the first-order to second-order transition. Since the localization of the Fermi energy in the density of state of the $3d$ band is very important, a comparison study has been done with the system $(\text{Er}_{1-x}\text{Tb}_x)\text{Ni}_2$. The concentration dependence of the lattice parameter differs a little from Vegard's law. Here we can infer from our results that all the magnetic transitions are second-order type. © 1996 American Institute of Physics. [S0021-8979(96)42708-7]

Our neutron-powder-diffraction experiment revealed that URhSi crystallizes in the orthorhombic TiNiSi (space group $Pnma$) structure and orders ferromagnetically at low temperatures with the U magnetic moments of $0.11 \mu_B$ aligned along the c axis. Anomalies in the temperature dependence of the magnetic susceptibility, specific heat and electrical resistivity indicate that URhSi orders below 9.5 K. The enhanced C_p/T value (extrapolated to 0 K) of 186 mJ/mol K^2 can be partially reduced in magnetic fields, which indicates a considerable magnetic contribution even at very low temperatures. The ferromagnetic ground state is documented also by magnetization measurements at low temperatures. The high-field magnetization data obtained on oriented powder reveal a strong magnetocrystalline anisotropy. All the results obtained on polycrystalline samples classify URhSi as an itinerant $5f$ ferromagnet with very reduced U magnetic moments. © 1996 American Institute of Physics. [S0021-8979(96)18408-8]

I. INTRODUCTION

The literature reports for URhSi either the CeCu_2 type structure^{1,2} (space group $Imma$) or its ordered version of the TiNiSi type³ ($Pnma$) similar to a number of other equiatomic ternary UTX (T =transition metal, X =Si or Ge) compounds.⁴ The differences between the x-ray or neutron-diffraction patterns for the two types of structures can be sometimes easily overlooked because the extra reflections, which appear for the ordered ternary version, are usually very weak. In both structures, the U atoms are coordinated in zigzag U chains within which each U atom has two nearest U neighbors at a distance of $d_{U-U} \sim 350 \text{ pm}$. In Hill's classification,⁵ such a value of d_{U-U} means that these compounds are situated in a critical region between localized and itinerant $5f$ electron behavior. The present contribution involves the determination of the type of the crystal structure and the magnetic ground state in the context of magnetic, transport and thermal properties.

II. EXPERIMENT

A polycrystalline sample of URhSi has been prepared by arc-melting stoichiometric amounts of the constituting elements of at least 99.9% purity under an argon atmosphere and subsequently annealed for four weeks at 900°C under vacuum. The purity and the composition homogeneity were checked by x-ray diffraction and by electron-microprobe analysis. The average composition of the major phase in the sample is deviating from the stoichiometric composition by less than 0.9 at. %. Nevertheless, a slight amount of URh_2Si_2 could be traced by the electron-microprobe analysis.

The magnetic susceptibility (M/H) in the temperature region 10–300 K and the low-temperature (down to 2 K) magnetization curves were measured in a Quantum Design

SQUID magnetometer in magnetic fields up to 5 T on a fine-powder sample with grains fixed in random orientation by diamagnetic glue.

The specific heat was measured by a standard semiadiabatic method in the temperature region 1.6–250 K and compared with the previous results³ from the temperature region 1.3–40 K.

The electrical resistivity was measured on a small bar-shaped sample by standard ac four-point method. Assuming large errors in the geometrical factor (in addition to the expected influence of internal microcracks) only the normalized electrical resistivity $\rho/\rho_{300 \text{ K}}$ is presented.

Neutron-diffraction data at 2.8, 24, and 80 K were obtained using the neutron powder diffractometer E6 installed at the Hahn–Meitner Institute using an incident neutron wavelength of 2.386 \AA . For these measurements URhSi was powdered and encapsulated into a vanadium container under He atmosphere. The recorded spectra were analyzed by means of the Rietveld profile procedure⁶ using the program FULLPROF.⁷ The neutron-scattering lengths were taken from Sears⁸ and uranium magnetic form factor from Delapalme.⁹

III. BULK MEASUREMENTS

The susceptibility (Fig. 1) is nearly field independent above 30 K. Below this temperature, the magnetization curves (Fig. 2) become progressively curved reflecting increasing ferromagnetic correlations.

The $1/\chi$ vs T dependence above 150 K is nearly linear and satisfies Curie–Weiss (CW) law

$$\chi = C/(T - \Theta_p) \quad (1)$$

with $C = (1.268 \pm 0.008) \cdot 10^{-5} \text{ m}^3/\text{mol K}$ ($\mu_{\text{eff}} = 2.84 \pm 0.01 \mu_B/U \text{ atom}$) and $\Theta_p = -164.3 \pm 0.9 \text{ K}$.

FIG. 1. Temperature dependences of the magnetic susceptibility measured in 0.01 T together with its reciprocal value (a), the specific heat in the representation C_p/T vs T (b) and the electrical resistivity of URhSi together with the temperature derivative of the electrical resistivity in the inset (c).

The strongly nonlinear part between 20 and 150 K can be roughly approximated by a modified CW law including a temperature independent term χ_0

$$\chi = C/(T - \Theta_p) + \chi_0 \quad (2)$$

with significantly lower value of Curie constant, a positive paramagnetic Curie temperature of 9.7 K and $\chi_0 \sim 10^{-8}$ m³/mol. Although, the applicability of both approaches for polycrystalline data of an anisotropic material is rather questionable some tentative conclusions can be made. The value

FIG. 2. Field dependence of the magnetization of the fixed powder of URhSi at various temperatures: 2 K (●), 5 K (▼), 10 K (■), 15 K (▲), and 20 K (◆). Some of the previous data measured at 4.2 K are also shown: free powder (○) and fixed powder (□).

of the effective moment from the high temperature fit, which can be taken as the upper limit in this material is much lower compared to free ion U^{3+} or U^{4+} expectation values in localized systems. We can take it as a good evidence of delocalization of $5f$ moments in the present system. The drastically different Θ_p values from the high- and low-temperature region point to very strong magnetocrystalline anisotropy in the paramagnetic range.

The magnetic ordering at $T_C = 9.5$ K is reflected by a relatively broad peak in the C_p/T vs T curve [Fig. 1(b)]. No other anomalies are seen between 1.6 and 250 K. The linear extrapolation of C_p/T vs T^2 from the region 1.6–8 K to $T = 0$ K gives a tentative γ value of 185.6 ± 1.3 mJ/mol K². A much better fit can, however, be obtained by the formula

$$C/T = \gamma + \beta^* T^2 + \delta^* T^2 \ln(T) \quad (3)$$

which involves the contribution of spin fluctuations through the additional logarithmic term. For the temperature region 1.6–9 K, the fitting parameters: $\gamma = 180.9 \pm 0.6$ mJ/mol K², $\beta^* = 2.4 \pm 0.1$ mJ/mol K⁴ and $\delta^* = -0.5 \pm 0.05$ mJ/mol K⁴ ln K were obtained. To estimate the magnetic entropy we tried to subtract the Debye function with a probable value of Debye temperature Θ_D . This task turns out to be very difficult. It seems impossible to assign one single value of Θ_D . The best agreement in the high-temperature part can be obtained for $\Theta_D = 290$ K together with the assumption of $\gamma = 20$ mJ/mol K². In this way, we obtained by integrating $(C/T - C_{\text{Debye}}/T)$ in the temperature region 0–100 K, a value of 9.1 J mol⁻¹ K⁻¹ for the magnetic entropy. This means a value of $1.58 R \ln 2$ or, through the expression $R \ln(2J+1)$, a value for J of 1.0. In fact, this value represents the estimated upper limit. The magnetic entropy connected with the magnetic transition is only a very small fraction of this value, the rest originates most probably from magnetic fluctuations.

The onset of magnetic ordering at $T_C = 9.5$ K is reflected also by the maximum in the temperature derivative of the electrical resistivity [Fig. 1(c)] near this temperature. The resistivity in the paramagnetic range is slightly decreasing with lowering temperature. It drops significantly below T_C , where also a quadratic temperature dependence with normalized parameters $\rho_0 = 0.4088 \pm 0.0004$ and the quadratic coefficient $A = 3.292 \pm 0.009 \cdot 10^{-3}$ K⁻² is observed.

The high-field magnetization⁶ measured at 4.2 K up to 35 T on a field-aligned powder sample saturates slowly and at 35 T it reaches $0.67 \mu_B/\text{f.u.}$ (M_{free}). A value of $0.31 \mu_B/\text{f.u.}$ is obtained by extrapolation to zero magnetic field. For a powdered sample with randomly oriented grains, somewhat smaller values of $0.52 \mu_B/\text{f.u.}$ (M_{fix}) and $0.23 \mu_B/\text{f.u.}$, respectively, are recorded. Although the magnetization is by far not yet saturated in 35 T the ratio $M_{\text{free}}/M_{\text{fix}} = 0.78$ can be taken as a supporting indication for an easy-plane anisotropy.

The low-field magnetization measured at different temperatures on a fixed-powder sample are shown in Fig. 2, where also some points from the previous high-field magnetization measurements (big open points) are displayed. It is clear that both data sets compare well and that hysteresis effects set in at low temperatures, as can be seen from the inset in Fig. 2 yielding a value of the remanent magnetization of $0.10 \mu_B/\text{f.u.}$

FIG. 3. Neutron-diffraction spectrum recorded at 80 K together with the best fit. The full line at the bottom represents the difference between the experimental data and the fit.

IV. NEUTRON DIFFRACTION RESULTS

Two possible crystallographic structures were considered: the CeCu_2 type of structure (space group $Imma$) and its ordered version TiNiSi (space group $Pnma$). The neutron-diffraction patterns obtained above the transition temperature, namely at 80 K (Fig. 3) and 24 K, can be indexed using the orthorhombic TiNiSi type of structure. Note that the lines indexed as 102, 111, 201, and 210 would be not present for the CeCu_2 type. The structural parameters determined at 80 K are summarized in Table I. The absence of any unindexed reflection proves the very low content of the URh_2Si_2 secondary phase indicated by the electron microprobe. A considerable improvement of fit is achieved by introducing a slightly higher fraction of U (0.9%) and a slightly lower atomic fraction of Rh (−0.8%). This is in a good agreement with the electron-microprobe analysis.

The spectrum recorded at 2.8 K (well below T_C inferred from bulk experiments) contains no additional reflections, but only additional magnetic contributions to the 101, 011, 200, 112, 202, and 211 nuclear Bragg reflections. This is consistent with identical magnetic and crystallographic unit cells. The magnetic structure was determined by fitting to the models possible within the experimental constrain. The best agreement was obtained for the model with all U moment parallel to the c axis, i.e., for the ferromagnetic model with the size of magnetic moments $0.11 \pm 0.02 \mu_B/U$ atom.

V. CONCLUSIONS

URhSi crystallizes in the orthorhombic TiNiSi -type of structure (space group $Pnma$) and orders ferromagnetically below 9.5 K with ordered U moments of about $0.11 \mu_B$. This rather small value in comparison with most UTX compounds together with magnetization, susceptibility, specific-heat, and

$c=745.842 \pm 0.079 \text{ pm}$				$R_B=2.35\%$	
$\chi^2=0.954$					

resistivity behavior suggests that the magnetism in URhSi is governed by strongly delocalized uranium $5f$ electron states. The origin of this itinerant behavior can be found mainly in the strong $5f$ -ligand hybridization.

The ordered U moment determined by the neutron-diffraction is much smaller than the value obtained from the high-field magnetization experiment. This fact points to field-induced moments in the latter experiment. The presence of magnetic fluctuations which play an important role at zero field even well above the transition temperature can be inferred from the bulk measurements. Studies on single-crystalline URhSi are highly desirable to get more specific information on substantial issues of magnetism in URhSi as are the magnetocrystalline anisotropy, orbital and spin moments, etc.

Magnetic and crystallographic properties of $\text{CrAs}_{1-x}\text{S}_x$ ($0 \leq x < 1$)

Takanobu Suzuki and Hideaki Ido

Faculty of Engineering, Tohoku Gakuin University, Tagajo 985, Japan

S substitution for As of CrAs compound has been successful up to 90 at. % for the first time in this work. The x-ray powder patterns and magnetic susceptibility curves have been observed for the compounds $\text{CrAs}_{1-x}\text{S}_x$ ($0 \leq x \leq 0.6$) in the temperature region from 80 K to 1100 K. It was found that the crystallographic transition from the orthorhombic MnP to the hexagonal NiAs type structure occurs with increase of temperature in the composition region $x \leq 0.5$. From the temperature dependence of lattice parameters, large spontaneous magnetostriction is found to occur mainly along the B axis of the compounds with small x . The magnetostriction decreases with x and disappears at $x = 0.35$. The Neel temperature have also been determined. The magnetic moments per Cr atom in the compounds with $x = 0.3, 0.4$, and 0.5 have been found to be within $2.95 \pm 0.10 \mu_B$, in the temperature region of the NiAs type structure. These data are compared with the previous ones of similar compounds. © 1996 American Institute of Physics. [S0021-8979(96)18508-4]

I. INTRODUCTION

It has been well known that the compound CrAs is a typical itinerant antiferromagnet with a double spiral magnetic order and shows a discontinuous change of the lattice parameters at the Neel temperature T_N (265 K).^{1,2} It is also very interesting that the compound undergoes the crystallographic transition from an orthorhombic MnP type to a hexagonal NiAs type at $T_i = 1100$ K.³ In our previous works,^{4,5} we studied the magnetic and crystallographic properties of a lot of substituted CrAs compounds by 3d elements and some pnictogen elements, and we found that T_N of the substituted compounds decreases drastically with the substitution except for the cases of Mn and Sb. Recently, we are successful for the first time to prepare S-substituted CrAs and investigated the magnetic and crystallographic properties of the samples with sulphur concentration x less than 0.2.⁶ In the present work, the substitution of sulphur is extended to $x = 0.9$ and x-ray and magnetic measurements have been performed for substituted compounds to compare the sulphur substitution effects with the other cases mentioned above.

II. SAMPLE PREPARATION

Compounds $\text{CrAs}_{1-x}\text{S}_x$ with various values of x between 0 and 0.9 were prepared by heating the mixture of desired masses of powdered Cr, As, and S in vacuum at 300 °C for three days, and then at 800 °C for three days. After quenching into water, they were crushed and mixed and heated again at 1000 °C for five days and then annealed at 300 °C for another two weeks. The crystal structure at room temperature has been found to be of the orthorhombic MnP type for the samples with $x \leq 0.4$ and of the hexagonal NiAs type in the case of $x > 0.4$ by powder x-ray methods. The relationship between MnP and NiAs type structures is explained in Fig. 1.

III. RESULTS AND DISCUSSION

The powder x-ray diffraction patterns were observed for the samples at various temperatures between 80 and 800 K in order to obtain the temperature dependence of lattice parameters A, B, and C and the crystallographic phase transition

temperature T_i from MnP to NiAs type structure. The lattice parameters were calculated by applying the least squares method to the observed patterns. The crystallographic transition temperature T_i has been determined by observing the temperature variation of the intensities of diffraction lines (210), (112), and (103) which disappear when the positional parameters u, v, x , and w become 0. Temperature dependencies of A, B and C axes of some representative samples are shown together with T_i in Figs. 2, 3, and 4, respectively.

As seen in Fig. 2, a discontinuous change of A axis, which means the negative spontaneous magnetostriction,⁶ occurs at T_N in the cases of $x = 0.0$ and 0.1 , and the discontinuous change disappears for the samples with x larger than 0.16.

It is seen from Fig. 3 that B axis of CrAs ($x = 0$) shows a discontinuous change at T_N , which means the positive spontaneous magnetostriction of 3.8%. The magnetostriction decreases linearly with x and changes its sign between $x = 0.3$ and 0.4 as seen in Fig. 3, where the negative striction is seen for the curve with $x = 0.4$.

FIG. 1. Crystal structure of MnP type. This structure becomes the hexagonal NiAs type, if the positional parameters u, v, x, w (w is not shown in the figure) disappear and the distortion parameter $\delta = C/\sqrt{3}B$ becomes 0.

FIG. 2. Temperature dependence of A axis for some representative samples.

Temperature dependence of C axis shown in Fig. 4 is similar to that of A axis in Fig. 2, and the magnitude of negative magnetostriction of C axis at T_N is about 1/4 of that of B axis in the case of $x=0$. The temperature dependence of the unit cell volume $V=A \cdot B \cdot C$ shown in Fig. 5 reflects mainly the temperature dependence of B axis.

The phase diagram of this system (Fig. 6) has been constructed on the basis of the results of crystallographic measurements mentioned above as well as the results of magnetic measurements which will be shown below. As shown in Fig. 6, the crystallographic transition temperature T_t decreases linearly with increase of x , while the Neel temperature T_N increases gradually with increase of x . Therefore, the temperatures T_t and T_N in the composition range $x \geq 0.38$ are considered to have the same value.

The temperature variations of magnetic susceptibility have been measured for several samples with different sul-

FIG. 4. Temperature dependence of C axis for some representative samples.

phur content in the temperature region between 80 and 1100 K. The reciprocal susceptibility vs temperature curves are shown in Fig. 7. The kink at 320 K and the broad minimum at around 800 K of the curve for $x=0.16$ correspond to T_N and T_t , respectively, shown in Fig. 6. The gradual decrease of $\chi^{-1}-T$ curve for $x=0.16$ between T_N and T_t is considered to be caused mainly by the decrease of the atomic positional parameters in MnP type structure.⁷ The curve for $x=0.3$ is similar to that of $x=0.16$. In the case of $x=0.5$, T_N and T_t are considered to coincide with each other, which is consistent with phase diagram shown in Fig. 6. The broad peak at around 120 K for $x=0.5$ cannot be explained at the present time. The $\chi^{-1}-T$ curve above T_t seems to be explained by the Curie-Weiss law, from which we obtained the magnetic moment per Cr atom $\mu_{Cr} (=2S_{Cr})$, where S_{Cr} is the chromium atomic spin) and the paramagnetic Curie tempera-

FIG. 3. Temperature dependence of B axis for some representative samples.

FIG. 5. Temperature dependence of the unit cell volume for some representative samples.

FIG. 6. The crystallographic and magnetic phase diagram of the system $\text{CrAs}_{1-x}\text{S}_x$.

ture θ_p as shown in the table in Fig. 7. In the case of the sample with $x=0.3$, the Curie-Weiss law seems to hold in the temperature region above 700 K, from which we obtained the values of $2S_{\text{Cr}}$ and θ_p in the same table. The anomalous behavior of $\chi^{-1}-T$ curve between T_t and $T=700$ K is difficult to explain at present. The $\chi^{-1}-T$ curve for $x=0.16$ in the temperature region above T_t is similar to $\chi^{-1}-T$ curve of $x=0.3$ between T_t and 700 K, therefore we did not apply the Curie-Weiss law in the case of $x=0.16$. The values of $2S_{\text{Cr}}$ and θ_p for $x=0.4$ are also given in the table in Fig. 7, though the $\chi^{-1}-T$ curve is not shown in Fig. 7. The magnetic moment per Cr atom obtained by the magnetic susceptibility measurements have been reported for the systems $\text{CrAs}_{1-x}\text{Sb}_x$,⁸ $\text{CrAs}_{1-x}\text{Se}_x$,⁹ $\text{Cr}_{1-x}\text{Ti}_x\text{As}$ (Ref. 3) and $\text{Cr}_{1-x}\text{Mn}_x\text{As}$.⁷ According to them, the Cr moment is in the range from 2.7 to 3.2 μ_B in the temperature region where the compounds take the NiAs type structure. The val-

FIG. 7. Temperature dependence of the inverse magnetic susceptibility for some representative samples.

ues shown in the inset of Fig. 7 are also in that range. On the other hand, the magnetic moment per Cr in CrAs at 4.2 K is 1.7 μ_B .¹⁰ The enormous difference in the Cr magnetic moment is believed to be caused by the crystal structure difference as well as the spin fluctuation effect.¹¹

Impact of criticality and phase separation on the spin dynamics of the one-dimensional t - J model

Shu Zhang and Gerhard Müller

Department of Physics, The University of Rhode Island, Kingston, Rhode Island 02881-0817

Joachim Stolze^{a)}

Physikalisches Institut, Universität Bayreuth, 95440 Bayreuth, Germany

The recursion method is used to determine the $T=0$ spin dynamic structure factor $S_{zz}(q, \omega)$ in the Luttinger liquid state and in the phase-separated state of the one-dimensional t - J model. As the exchange coupling increases from zero, the dispersions and line shapes of the dominant spin excitations are observed to undergo a major metamorphosis between the free-fermion limit and the onset of phase separation. The familiar two-spinon spectrum of the Heisenberg antiferromagnetic chain emerges gradually in the strongly phase-separated state. © 1996 American Institute of Physics. [S0021-8979(96)18608-0]

The t - J model for strongly correlated electrons has been widely used as a prototypical system for the study of the interplay between charge and spin degrees of freedom.¹ For a one-dimensional (1D) lattice of N sites the Hamiltonian reads

$$H_{t-J} = -t \sum_{\sigma=\uparrow, \downarrow} \sum_{l=1}^N \{ \tilde{c}_{l,\sigma}^\dagger \tilde{c}_{l+1,\sigma} + \tilde{c}_{l+1,\sigma}^\dagger \tilde{c}_{l,\sigma} \} + J \sum_{l=1}^N \left\{ \mathbf{S}_l \cdot \mathbf{S}_{l+1} - \frac{1}{4} n_l n_{l+1} \right\} \quad (1)$$

with $\tilde{c}_{l,\sigma} = c_{l,\sigma}(1 - n_{l,-\sigma})$, $n_l = n_{l,\uparrow} + n_{l,\downarrow}$, $n_{l,\sigma} = c_{l,\sigma}^\dagger c_{l,\sigma}$, $S_l^z = (n_{l,\uparrow} - n_{l,\downarrow})/2$, and $S_l^\pm = \tilde{c}_{l,\uparrow}^\dagger \tilde{c}_{l,\downarrow}$. Here we consider the quarter-filled-band case ($N_e = N/2$ electrons).

The hopping term amounts to an effectively repulsive force between electrons on nearest-neighbor sites,² and the exchange term represents an attractive force if these two electrons have opposite spins. As the exchange interaction increases from zero, the ground state of H_{t-J} undergoes a transition, at $J/t \approx 3.2$, from a Luttinger liquid state to a phase-separated state.³⁻⁵ In the Luttinger liquid state, both the charge correlations (at $q = \pi$) and the spin correlations (at $q = \pi/2$) are critical. The transition, which is driven by the spin coupling, produces charge long-range order (at $q = 0$) combined with a new type of spin criticality (at $q = \pi$).

The focus of this study is on the frequency-dependent spin fluctuations of H_{t-J} as they manifest themselves in the $T=0$ spin dynamic structure factor

$$S_{zz}(q, \omega) = \frac{1}{N} \sum_{l,m} e^{-iqm} \int_{-\infty}^{+\infty} dt e^{i\omega t} \langle S_l^z(t) S_{l+m}^z \rangle. \quad (2)$$

For the calculation of this quantity, we employ the recursion method⁶ in combination with a *strong-coupling continued-fraction analysis*.^{7,8} The recursion method in the present context is based on an orthogonal expansion of the wave function $|\Psi_q^z(t)\rangle = S_q^z(-t)|G\rangle$, where $S_q^z = N^{-1/2} \sum_l e^{iql} S_l^z$ is the spin fluctuation operator, and $|G\rangle$ is the finite-size ground-state wave function of Eq. (1). After some intermediate steps,

the algorithm produces a sequence of continued-fraction coefficients $\Delta_1^z(q), \Delta_2^z(q), \dots$ for the relaxation function,

$$c_0^{zz}(q, z) = \frac{1}{z + \frac{\Delta_1^z(q)}{z + \frac{\Delta_2^z(q)}{z + \dots}}}, \quad (3)$$

which is the Laplace transform of the symmetrized correlation function $\Re\langle S_q^z(t) S_{-q}^z \rangle / \langle S_q^z S_{-q}^z \rangle$. The $T=0$ spin dynamic structure factor (2) is then obtained from Eq. (3) via the relation

$$S_{zz}(q, \omega) = 4 \langle S_q^z S_{-q}^z \rangle \Theta(\omega) \lim_{\epsilon \rightarrow 0} \Re[c_0^{zz}(q, \epsilon - i\omega)]. \quad (4)$$

In a previous paper⁹ we have used the recursion method together with a *weak-coupling continued-fraction analysis* for a study of the charge dynamic structure factor in the Luttinger liquid phase of the t - J model. The spin dynamics poses a far greater challenge. Very few explicit results seem to exist.¹⁰ One key spin dynamical property in the Luttinger liquid phase can be inferred from the asymptotic behavior of the static spin correlations as proposed in previous work:^{4,5}

$$\langle S_l^z S_{l+m}^z \rangle \sim B_1 \frac{1}{m^2} + B_2 \frac{\cos(\pi m/2)}{m^{\eta_p/4+1}}, \quad (5)$$

where η_p is the exponent which also governs the algebraic decay of the ($q = \pi$) oscillations, $\sim \cos(\pi m)/m^{\eta_p}$, in the static charge correlation function $\langle n_l n_{l+m} \rangle$. This exponent is known to assume the value $\eta_p = 2$ in the free-fermion limit ($J/t = 0^+$). It increases linearly, $\Delta \eta_p \approx 0.40 J/t$, in the weak-coupling regime,^{3,9} assumes the value $\eta_p \approx 3.4$ at $J/t = 2$ (supersymmetric case),¹¹ and diverges at the endpoint, $J/t \approx 3.2$, of the Luttinger liquid state.³

The oscillatory term in Eq. (5) implies that the dynamically relevant excitation spectrum of $S_{zz}(q, \omega)$ is gapless at $q = \pi/2$. The spectral-weight distribution of the spin dynamic structure factor at this critical wave number can then be predicted (under mild assumptions) to have a singularity of the form

$$S_{zz}(\pi/2, \omega) \sim \omega^{\eta_p/4-1}. \quad (6)$$

The infrared exponent starts out negative in the free-fermion limit, $\sim \omega^{-1/2}$, increases monotonically with increasing J/t ,

FIG. 1. Spin dynamic structure factor $S_{zz}(q, \omega)$ at $T=0$ for $q=2\pi l/12$, $l=0, \dots, 6$ of the 1D t - J model with $t=1$ and $J=0.1$ in the Luttinger liquid phase near the free-fermion limit.

and then diverges at $J/t \approx 3.2$, where phase separation sets in. A landmark change in $S_{zz}(\pi, \omega)$ is expected to occur at the point where the infrared exponent switches sign (from negative to positive). This happens for $\eta_p=4$, which corresponds to the coupling strength $J/t \approx 2.3$.

Our results for $S_{zz}(q, \omega)$ indicate that the Luttinger liquid phase of the t - J model can be divided into two regimes with distinct spin dynamical properties. As a representative result of the first regime ($0 < J/t \leq 1$), we show in Fig. 1 $S_{zz}(q, \omega)$ as a continuous function of ω and a discrete function of the q values realized in a system of $N=12$ sites with coupling strength $J/t=0.1$.

All results presented here have been calculated via a strong-coupling continued-fraction reconstruction from the coefficients $\Delta_1, \dots, \Delta_6$ and a Gaussian terminator. The Δ_k 's have been extracted via the recursion method from the ground-state wave function for $N=12$, which in turn has been computed via the conjugate-gradient method. The entire procedure was explained in Ref. 7.

Throughout the Brillouin zone except at small q we observe a well-defined dynamically relevant spin mode with a $|\cos q|$ -like dispersion as indicated by the full circles. Near the critical wave number, $q=\pi/2$, the function $S_{zz}(q, \omega)$ may exhibit a power-law divergence of the form $\sim [\omega^2 - c^2(\pi/2 - q)^2]^{(\eta_p/4 - 1)/2}$, similar to what has been observed at the critical wave number in other Luttinger liquids.¹² At long wavelengths the spectral weight in $S_{zz}(q, \omega)$ is concentrated at fairly low frequencies. Data for longer chains will be needed for a quantitative analysis of the spin dispersions at small q in this regime.

As the exchange coupling increases toward $J/t \approx 1$, the following changes in the spectral-weight distribution of $S_{zz}(q, \omega)$ can be identified:

(i) The amplitude of the $|\cos q|$ -like dispersion grows with increasing J/t . The gradual upward shift of the peak position in $S_{zz}(q, \omega)$ is accompanied by a significant increase in linewidth. For the $q=\pi$ spin mode this is contrary to what one expects under the influence of an antiferromagnetic exchange interaction of increasing strength. That trend changes at stronger coupling as we shall see.

FIG. 2. Line shape at $q=\pi/2$ of the spin dynamic structure factor $S_{zz}(q, \omega)$ at $T=0$ for various values of J in the Luttinger liquid state of the 1D t - J model with $t=1$ (main plot). Line shape at $q=\pi$ for various values of J in the phase-separated state (inset).

(ii) The intensity of the central peak in $S_{zz}(\pi/2, \omega)$ weakens gradually. This is illustrated in the main diagram of Fig. 2. The peak turns shallow and then vanishes altogether. This property of our data reflects the gradual weakening and ultimate disappearance of the power-law divergence (6), given the (approximately known) J/t dependence of the infrared exponent.

As the coupling strength increases past the value $J/t \approx 1$, the spin modes which dominate $S_{zz}(q, \omega)$ in the first regime of the Luttinger liquid phase broaden rapidly and lose their distinctiveness. There is a crossover region between the first and second regimes, which roughly comprises the coupling range $1 \leq J/t \leq 2$. Over that range, the spectral weight in $S_{zz}(q, \omega)$ is distributed over a broad structure with rapidly shifting peaks.

At the end of the crossover region, a new type of spin mode with an entirely different kind of dispersion has gained prominence in $S_{zz}(q, \omega)$, and it stays dominant throughout the remainder of the Luttinger liquid phase. This is illustrated in Fig. 3 by a plot of $S_{zz}(q, \omega)$ for a J/t value near the onset of phase separation. The representation is the same as in Fig. 1 except for the different frequency scale.

The dispersion of these new spin modes, as shown by the full circles, does no longer have a soft mode at $q=\pi/2$. At $J/t \sim 2.0$ the dispersion has a $|\sin(q/2)|$ -like shape, i.e., a smooth maximum at $q=\pi$ and a tendency to approach zero linearly as $q \rightarrow 0$. As J/t increases toward the transition point, the peak positions in $S_{zz}(q, \omega)$ gradually shift to lower values of ω/J (with t held fixed). The shift proceeds more rapidly at q near π than at smaller q , which has the consequence that the maximum in the dynamically relevant spin dispersion starts to move away from $q=\pi$ toward $q=\pi/2$.

FIG. 3. Spin dynamic structure factor $S_{zz}(q, \omega)$ at $T=0$ for $q=2\pi l/12$, $l=0, \dots, 6$ of the 1D t - J model with $t=1$ and $J=2.75$ in the Luttinger liquid phase near the onset of phase separation.

This trend from a $|\sin(q/2)|$ -like toward a $|\sin q|$ -like dispersion persists in the phase-separated state ($J/t > 3.2$).

The evolution of the spectral-weight distribution in $S_{zz}(\pi, \omega)$ from a well-defined mode at $\omega/J \approx 1.4$ near the onset of phase separation toward a soft mode in the strongly phase-separated state is shown in the inset to Fig. 2. By contrast, the spectral weight in $S_{zz}(\pi/2, \omega)$, which has been slowly shifting toward lower values of ω/J in the second regime of the Luttinger liquid phase, now starts to move back out to higher frequencies in the phase-separated state (not shown here). The single-peak structure grows taller, the linewidth shrinks somewhat, and the peak position settles at $\omega/J \approx 1.57$.

All these properties and trends reflect or foreshadow the much better understood $T=0$ dynamical properties of the 1D $s=1/2$ Heisenberg antiferromagnet—the end product of the

t - J model in the completely phase-separated state. The spin dynamic structure factor $S_{zz}(q, \omega)$ under these circumstances is known to be dominated by a continuum of two-spinon excitations with a lower boundary $\epsilon_L(q) = (\pi/2)J|\sin q|$, where the spectral-weight distribution has a divergent singularity, and an upper boundary $\epsilon_U(q) = \pi J|\sin(q/2)|$, where the spectral-weight distribution becomes very small.^{7,8,13}

Rapid loss of magnetic order in Ni on alloying with Cr, Mo, Re, and Si

V. Suresh Babu, A. S. Pavlovic, and Mohindar S. Seehra^{a)}

Physics Department, West Virginia University, Morgantown, West Virginia 26506-6315

In this article, the variation of the Curie temperature T_c and the magnetic moment μ of Ni in the fcc alloys $\text{Ni}_{1-x}\text{M}_x$ ($M=\text{Cr, Mo, Re, and Si}$) are reported for concentrations x between 0 and 15 at. %. The decrease of T_c and μ with x reported earlier for NiCr alloys are also observed for the NiMo, NiRe, and NiSi alloys. The initial rates of decreases are about 60 K/at. % for T_c and 0.05 μ_B /at. % for μ , leading to critical concentration $x_c \approx 13\%$ above which ferromagnetism disappears. Qualitatively, these decreases may be understood in terms of transfer of outer shell electrons of M atoms to the $3d\downarrow$ band of Ni in the alloys. However, a quantitative calculation of x_c is not yet available. © 1996 American Institute of Physics. [S0021-8979(96)18708-7]

INTRODUCTION

In this paper, we present experimental results on the variation of the Curie temperature T_c and magnetic moment μ of Ni as it is alloyed with Cr, Mo, Re, and Si for concentrations up to 15 at. % of the dopants. The variations of the T_c 's of $\text{Ni}_{1-x}\text{Cr}_x$ alloys have been reported by a number of research groups¹⁻⁵ and the results have also been discussed theoretically.⁶⁻⁹ However results presented here for the Mo, Re, and Si alloys are new and they provide an opportunity to examine in further detail the theoretical interpretations advanced for the NiCr alloys. Details of these investigations are presented below.

EXPERIMENTAL PROCEDURES

The binary alloys $\text{Ni}_{1-x}\text{M}_x$ ($M=\text{Cr, Mo, Re, and Si}$) were prepared by arc melting from four nine pure materials for the compositions $x=3, 6, \text{ and } 9$ at. % for Si and $x=5, 8, 10, 12, \text{ and } 15$ at. % for Cr, Mo, and Re using oxygen-free argon atmosphere. All samples were homogenized by remelting and turning over several times, followed by annealing in argon for 120 h at 1000 °C. Samples were then cut for x-ray diffraction (XRD), magnetic measurements, and for measurements of thermal expansion for temperatures to 1000 °C. Results of the thermal expansion and their comparison with the results from molecular dynamics simulations have been reported elsewhere.¹⁰ Here we concentrate on the magnetic properties of these materials. XRD patterns were recorded using a Rigaku/DMax diffractometer ($\text{Cu } K_\alpha$ radiation) in the 2θ range of 20° – 90° at a scan speed of $1^\circ/\text{min}$ and a sampling interval of 0.02° . Magnetic studies reported here were carried out using a SQUID magnetometer (Quantum Design model MPMS) with samples in the shape of square discs with masses of about 10–80 mg and magnetic fields applied in the plane of the discs. The magnetic susceptibilities $\chi=M/H$ were measured in $H=50$ Oe in most cases.

RESULTS AND DISCUSSION

Only samples with single fcc phase as determined by XRD were investigated further. The lattice constant a measured from the XRD peaks using the standard iterative method¹¹ is plotted against the concentration x of the various

alloys in Fig. 1. From the linear fits in Fig. 1, the atomic radii calculated assuming close packing are 1.246, 1.290, 1.382, and 1.401 Å for Ni, Cr, Re, and Mo, respectively. These results are in excellent agreement with the literature values,¹² suggesting that in the alloys, Cr, Re, and Mo occupy substitutional positions. On the other hand, for the Si case, there is no significant change in the lattice constant with concentration suggesting perhaps interstitial occupancy.

In Fig. 2, we show on a semilog scale the temperature variations of χ (50 Oe) for Ni and representative alloys where the solid line for Ni is a fit to the Curie–Weiss law $\chi=C/(T-T_c)^\gamma$ and where T_c was determined by linear extrapolation of the data¹³ from above and below the transition. Our measured values for Ni are $T_c=632\pm 2$ K and $\gamma\approx 1.25\pm 0.02$, in good agreement with the reported values of $T_c\approx 630$ K and $\gamma\approx 1.35\pm 0.02$.¹ This good agreement of T_c values at these high temperatures provides a good check on the temperature calibration of our magnetometer whereas γ values might have been affected by the nonspherical shapes of our samples. The latter fact can affect the magnitudes of low field χ near T_c due to demagnetization factors when χ approaches unity. In any case, the emphasis of the present work is on the variation of T_c and saturation magnetization M_0 as a function of the atomic concentration x in $\text{Ni}_{(1-x)}\text{M}_x$.

FIG. 1. Measured lattice parameter of the fcc phase is plotted against x in $\text{Ni}_{1-x}\text{M}_x$ for $M=\text{Si, Cr, Mo, and Re}$. The straight line fits yield the listed atomic radii assuming close packing.

^{a)}Corresponding author.

FIG. 2. Measured magnetic susceptibility $\chi = M/H$ ($H=50$ Oe) vs temperature for representative samples. The arrows point to the estimated T_c .

For some samples near the critical x for ferromagnetism, a definite kink in low-field χ vs T is not observed. In those cases, we used the Arrott plots of M^2 vs H/M (Fig. 3) to estimate T_c by linear extrapolation from the high H/M values (at T_c , the extrapolated curve passes through the origin).¹ A plot of T_c 's so evaluated versus the concentration x is shown in Fig. 4 where we have also included data from the literature on the NiCr system. Our observed variations of T_c with x for NiCr alloys are in excellent agreement with those reported by Besnus *et al.*² and Simpson *et al.*⁵ (solid line in Fig. 4) yielding critical concentration $x_c \approx 13\%$. For the NiSi, NiRe, and NiMo alloys, T_c vs x curves are essentially similar to that for the NiCr alloys in that in all cases T_c falls toward zero at a rate of about 60 K/at. % although there are clearly slight differences between the different cases. For $x > 10\%$ there are deviations from this linearity as also noted by Besnus *et al.*² and $x_c \approx 13\%$.

Next we consider the variation of saturation magnetization M_0 or equivalently the magnetic moment μ on the Ni atom as a function of x . M_0 was estimated from the M vs H plots carried out to 20 kOe at 5 K, and in some cases with low T_c compositions at 2 K. For a Ni wafer, our measured value of $M_0 = 60.55$ emu/g translates into $\mu = 0.636 \mu_B$, in excellent agreement with the reported value of $0.642 \mu_B$.¹ The variation of μ vs x is plotted in Fig. 5 for all our samples

FIG. 3. The Arrott plot of M^2 vs H/M for the $\text{Ni}_{0.9}\text{Re}_{0.1}$ alloy. A $T_c = 80$ K is estimated as discussed in text.

FIG. 4. Variation of the Curie temperature T_c with concentration x for different alloys. The solid line is for the $\text{Ni}_{1-x}\text{Cr}_x$ system based on literature values whereas lines joining the points are for visual aid.

as well as those reported in literature.^{2,4} Again the drop in μ with increasing x at a rate of about $0.05 \mu_B/\text{at. \%}$ is obvious, with substantial drop in this rate of decrease for $x > 10\%$. From the data in Figs. 4 and 5, it is clear that alloying of Ni with Cr, Re, Mo, and Si affects the magnetic moment μ and T_c of Ni in essentially similar fashion, viz., rapid lowering of μ and T_c as x is increased, so that above the critical concentration $x_c \approx 13\%$, magnetic order is absent at a nonzero temperature.

There are small yet noticeable differences between the different systems investigated here. For example, T_c for the Re and Mo alloys tend to be somewhat lower than those for the Si and Cr alloys for the same x (Fig. 4) whereas μ for the Si alloys for the same x is lower than the other cases. Of course, Re and Mo are larger atoms and they produce larger change in the lattice constants (Fig. 1) so that these observations may be related. A plot of M_0^2 vs T_c yields essentially a linear behavior (Fig. 6) for high T_c compositions whereas the points for samples with $x > 10\%$ show a significant deviation from this linearity, as also noted by Besnus *et al.*²

The band theory of the ferromagnetism of Fe, Co, and Ni has been the subject of discussion for several decades⁶⁻⁹ and a simple picture is presented by Kittel.¹² The exchange-split

FIG. 6. A plot of M_0^2 against T_c . Departures from linearity are observed for compositions close to x_c .

$3d\downarrow$ and $3d\uparrow$ bands below T_c leads to 0.54 holes/atom of $3d\downarrow$ band of Ni to agree with the experimental value of μ . Qualitatively the alloying of Ni with Cr, Re, Mo, and Si may result in the partial transfer of the outer shell electrons of these atoms into the empty $3d\downarrow$ band, thus lowering both μ and, consequently, T_c . To the best of our knowledge, a theo-

retical calculation to explain the experimental result of $x_c \approx 13\%$ observed here for the four alloy systems is not yet available. Hopefully, these experimental results would stimulate such a calculation.

Magnetic properties of the $\text{SmMn}_2(\text{Ge}_{1-x}\text{Si}_x)_2$ system

Shibaji Saha and Naushad Ali

Department of Physics and Molecular Science Program, Southern Illinois University at Carbondale,
Carbondale, Illinois 62901

Magnetization and thermal expansion measurements have been carried out on the polycrystalline $\text{SmMn}_2(\text{Ge}_{1-x}\text{Si}_x)_2$ system ($x=0.00, 0.01, 0.02, 0.03, 0.05, 0.08, 0.10, 0.12$, and 0.15) to study its magnetic properties. It is found that the temperature range of stability of the antiferromagnetic region increases with the increase of Si content. This behavior is explained as a decrease in the Mn–Mn intralayer separation. Ferro- to antiferromagnetic (T_2) and antiferro- to ferromagnetic (T_1) transitions are found to be first order for all the samples up to $x=0.10$. For $x=0.15$ sample the antiferro- to ferromagnetic (T_1) transition is of first order while the ferro- to antiferromagnetic (T_2) transition appears to be second order. A magnetic phase diagram of $\text{SmMn}_2(\text{Ge}_{1-x}\text{Si}_x)_2$ has been determined. © 1996 American Institute of Physics. [S0021-8979(96)18808-3]

INTRODUCTION

Intermetallic ternary compounds, RMn_2X_2 (R =rare earths and $X=\text{Si}, \text{Ge}$),^{1,2} have attracted considerable attention. The compounds are body centered tetragonal and form in ThCr_2Si_2 crystal structure. The structure is formed by stacking of atomic layers perpendicular to the c axis following the sequence $\cdots R-X-Mn-X-R \cdots$. The magnetic properties of RMn_2X_2 compounds are very sensitive to Mn–Mn intralayer distance, $R_{\text{Mn-Mn}}^a$. Compounds with $R_{\text{Mn-Mn}}^a \leq 0.2865$ nm are antiferromagnetic while they are ferromagnetic for $R_{\text{Mn-Mn}}^a \geq 0.2865$ nm. Among these compounds, SmMn_2Ge_2 exhibits the most interesting properties, mainly because its $R_{\text{Mn-Mn}}^a$ value is close to the critical value. SmMn_2Ge_2 is ferromagnetic with a Curie temperature of 340 K. As the sample is cooled below 340 K, the ferromagnetic phase persists down to 150 K, at which point it reorders antiferromagnetically. This antiferromagnetic phase is retained down to 100 K. As the sample is cooled below 100 K, it enters to a ferromagnetic phase. The antiferromagnetic phase is thought to be very sensitive to the Mn–Mn intralayer separation.³

In an effort to understand the nature of the magnetic properties in SmMn_2Ge_2 , Duraj *et al.*^{4,5} have studied $\text{Sm}_{1-x}\text{Gd}_x\text{Mn}_2\text{Ge}_2$ and $\text{Sm}_{1-x}\text{Y}_x\text{Mn}_2\text{Ge}_2$. It has been observed that with the increase of Y and Gd content, the temperature range of stability of the ferromagnetic phase decreases while that of the antiferromagnetic phase increases. This effect has been related to a decrease in intralayer distance, $R_{\text{Mn-Mn}}^a$, with increasing concentration of Gd or Y. Another study by Duraj *et al.*⁶ on $\text{Sm}_{0.09}\text{Nd}_{0.1}\text{Mn}_2\text{Ge}_2$ shows that with the increase of external pressure, it is possible to regain the “lost” antiferromagnetic phase. All the above studies show that transition from the ferro- to the antiferromagnetic phase is strongly coupled with interatomic distance ($R_{\text{Mn-Mn}}^a$).

Recently, we made an effort⁷ to replace the Mn content partially with Cr in SmMn_2Ge_2 . Our study shows that by the addition of 5% Cr in place of Mn, the antiferromagnetic region in $\text{Sm}(\text{Mn}_{1-x}\text{Cr}_x)_2\text{Ge}_2$ system disappears. In the present study, we have tried to partially replace the nonmagnetic contributor, Ge, in SmMn_2Ge_2 by Si. Magnetization and thermal expansivity measurements have been performed

on $\text{SmMn}_2(\text{Ge}_{1-x}\text{Si}_x)_2$ for $x=0.00$ to $x=0.15$. Magnetization measurements as a function of temperature and magnetic field have been utilized to determine the magnetic phase diagram of the $\text{SmMn}_2(\text{Ge}_{1-x}\text{Si}_x)_2$ system.

EXPERIMENTAL DETAILS

Samples were synthesized by arc melting in an Ar atmosphere of the proper amounts of the constituent elements. An excess amount of Mn was added to compensate for its weight loss due to volatility during melting. The purity of the elements were 99.9% for Sm, 99.99% for Mn and Cr, and 99.999% for Ge. During the melting process the ingots were turned over and remelted 4 to 5 times to ensure homogeneity. Samples were then wrapped in Ta foil and annealed under vacuum ($\sim 10^{-7}$ Torr) at 800 °C for 7 days. Magnetization measurements were carried out by means of a SQUID magnetometer (Quantum Design, CA) over the temperature range of 5–395 K and in an applied magnetic field range of 0.1–55 kG. Thermal expansion measurements were made using a capacitance dilatometer over the temperature range of 5–290 K.

EXPERIMENTAL RESULTS AND DISCUSSION

The temperature dependence of magnetization of $\text{SmMn}_2(\text{Ge}_{1-x}\text{Si}_x)_2$ for $x=0.00$ to 0.15 in an applied field of 100 G is shown in Fig. 1. The samples were cooled down from room temperature in zero applied magnetic field before magnetization measurements. For $x=0.00$, i.e., for SmMn_2Ge_2 , the transition temperatures are found to be at $T_c=339$ K for the para- to ferromagnetic transition, at $T_2=158$ K for the ferro- to antiferromagnetic transition, and at $T_1=103$ K for the reentrant ferromagnetic transition. For $x=0.00$ sample we also notice that there is a clear sharp peak at 148.5 K. This behavior was reported previously^{7,8} and the temperature was labeled as spin-reorientation temperature (T_{SR}). It was explained as a spin reorientation of the Mn moments from the c axis $\langle 001 \rangle$ direction to the basal plane $\langle 110 \rangle$ direction, which appears as a stable antiferromagnetic phase down to T_1 . This T_{SR} is also observed clearly for the $x=0.01$ sample. This spin-reorientation behavior persists for all the samples up to $x=0.15$. The inset of Fig. 1 shows the spin-reorientation transition for some of the samples. It

FIG. 1. Magnetization of $\text{SmMn}_2(\text{Ge}_{1-x}\text{Si}_x)_2$ ($x=0.00-0.15$) samples as a function of temperature at 100 G. Inset shows magnified view of the spin-reorient transitions.

shows that the T_{SR} does not change significantly with increasing Si concentration, but that transition is not as sharp in higher concentration Si samples as that of pure SmMn_2Ge_2 . From Fig. 1 what we also notice is that the increase of Si content in $\text{SmMn}_2(\text{Ge}_{1-x}\text{Si}_x)_2$ has the effect of increasing the temperature range of the antiferromagnetic phase. For example, the 55 K temperature range of the antiferromagnetic phase for the sample with $x=0.00$ increases to about 220 K for sample with $x=0.15$. The other thing to notice is that the ferro- to antiferromagnetic transition (T_2) becomes broader instead of sharp transitions observed for the samples with lower Si content.

Fujii *et al.*³ suggested in the study of single crystal SmMn_2Ge_2 that at the ferro- to antiferromagnetic transition, (T_2) the $R_{\text{Mn-Mn}}^a$ distance becomes smaller than the critical value of 0.2865 nm. This is why the sample transforms from the ferromagnetic to antiferromagnetic phase. For SmMn_2Ge_2 it has been demonstrated⁹ by the application of external pressure on the temperature-dependent ac susceptibility measurements that ferro- to antiferromagnetic (T_2) and antiferro- to ferromagnetic (T_1) transitions are very sensitive to the intralayer distance. What Duraj *et al.*⁹ have found is that, with the increase of external pressure, the temperature range of the antiferromagnetic phase of SmMn_2Ge_2 widens. Another study,⁴ in which chemical pressure was used by substituting Gd for Sm in SmMn_2Ge_2 , also shows the broadening of the antiferromagnetic region. In the case of $\text{SmMn}_2\text{Ge}_{1-x}\text{Si}_x$, it is very likely that increasing the Si content effectively reduces the Mn-Mn in-plane distance. Consequently, as the Si content in $\text{SmMn}_2(\text{Ge}_{1-x}\text{Si}_x)_2$ is increased, the antiferromagnetic coupling becomes stronger. This effect results in a wider temperature range of the antiferromagnetic phase of $\text{SmMn}_2(\text{Ge}_{1-x}\text{Si}_x)_2$.

Figure 2(a) shows the magnetic field dependence of magnetization at 5 K of $\text{SmMn}_2(\text{Ge}_{1-x}\text{Si}_x)_2$ compounds for $x=0.00$ to $x=0.15$. For all the samples magnetization increases sharply up to about 0.5 T. Above 1.0 T magnetization increases linearly up to the maximum applied field of 5.5 T and never saturates. Magnetization values at the maximum

FIG. 2. Magnetization as a function of applied magnetic field at 5 K (a) and at 250 K (b). Insets show the magnetization values at the maximum field (5.5 T) as a function of Si concentration.

applied field (5.5 T) are plotted against Si content in the inset of Fig. 2(a). It shows that magnetization does not change much for the samples up to $x=0.10$ and then drops fast.

Figure 2(b) shows the magnetic field dependence of magnetization of $\text{SmMn}_2(\text{Ge}_{1-x}\text{Si}_x)_2$ at 250 K for $x=0.00$ to $x=0.15$. The temperature 250 K falls in the high-temperature ferromagnetic phase (from M vs T data). Changes in magnetization for samples up to $x=0.10$ are broad for applied magnetic field up to 3.0 T and then increase slowly for field up to 5.5 T. Magnetization is not saturated for any sample at the maximum applied field of 5.5 T. The M vs H behavior at 250 K of $x=0.15$ sample shows its proximity in the antiferromagnetic phase. The magnetization values at the maximum applied field (5.5 T) are plotted against Si content in the inset of Fig. 2(b). It shows that magnetization decreases very slowly with the increase of Si content for up to $x=0.10$ then drops faster.

To know how the thermal expansion varies with temperature for different samples of $\text{SmMn}_2(\text{Ge}_{1-x}\text{Si}_x)_2$ and to know the order of the phase transitions, thermal expansion measurements were performed. Results are plotted in Fig. 3.

FIG. 3. Relative thermal expansivity $\Delta l/l$ of $\text{SmMn}_2(\text{Ge}_{1-x}\text{Si}_x)_2$ samples as a function of temperature for $x=0.00$ to 0.15.

Thermal expansion behavior of the samples reflects the corresponding magnetic properties (Fig. 1). Also, the transition temperatures (T_1 and T_2) found from magnetization and thermal expansion measurements agree for every sample. The antiferro- to ferromagnetic transitions (T_1) for samples with $x=0.00$ to $x=0.15$ shows a step change in thermal expansion measurements. This implies that the type of the phase transition at T_1 is first order. Similarly, ferro- to antiferromagnetic transitions (T_2) are of first order for $x=0.00$ to $x=0.10$ samples. However, for $x=0.15$ sample, the slope change at the phase transition suggests that the antiferro- to ferromagnetic phase transition (T_2) is most likely of second order. The anomalies found for all the samples in the temperature range 220 to 235 K came from the background. Thermal expansion data could also indicate the change in lattice parameters. The largest change in thermal expansion data occurs at the two first order phase transitions. Actual lattice parameters of SmMn_2Ge_2 and $\text{Sm}_{1-x}\text{Gd}_x\text{Mn}_2\text{Ge}_2$ at different temperatures were determined by x-ray studies.^{9,4} For both compounds it was found that at the ferro- to antiferromagnetic (T_2) and antiferro- to ferromagnetic transitions (T_1) the lattice constant a goes through a discontinuity. In the present study, the step changes in thermal expansion data (at T_1 and T_2 temperatures) of $\text{SmMn}_2(\text{Ge}_{1-x}\text{Si}_x)_2$ suggest a discontinuity in the lattice constant " a ."

A phase diagram of $\text{SmMn}_2(\text{Ge}_{1-x}\text{Si}_x)_2$ is shown in Fig. 4. It shows that T_c essentially remains constant with increasing Si concentration. The ferro- to antiferromagnetic transition temperature (T_2) increases almost linearly with the increase of Si concentration. The antiferro- to ferromagnetic transition temperature (T_1) decreases almost linearly with the increase of Si concentration. The range of the antiferromagnetic phase increases sharply with increasing Si content. Temperature range of both ferromagnetic phases decrease with the increase of Si content. The spin-reorientation temperature T_{SR} does not change significantly for any of the samples.

SUMMARY

We have studied the magnetic and thermal properties of polycrystalline $\text{SmMn}_2(\text{Ge}_{1-x}\text{Si}_x)_2$ system for $x=0.00$ to

FIG. 4. Magnetic phase diagram of $\text{SmMn}_2(\text{Ge}_{1-x}\text{Si}_x)_2$. It shows the different magnetic phases, e.g., paramagnetic (PM), ferromagnetic (FM), and antiferromagnetic (AFM), that are present at different temperatures.

$x=0.15$. It is found that the temperature range of stability of the antiferromagnetic phase increases with the increase of Si content. This behavior is explained as a consequence of the possible decrease in the in-plane Mn-Mn distance. We have demonstrated again that the magnetic properties of SmMn_2Ge_2 and the related compounds are very sensitive to the interatomic distances. We have determined the magnetic phase diagram of $\text{SmMn}_2(\text{Ge}_{1-x}\text{Si}_x)_2$.

The substitution of small amounts of Mn^{2+} by Cu^{2+} or Cd^{2+} ions in the linear chain antiferromagnet $(\text{CH}_3\text{NH}_3)\text{MnCl}_3 \cdot 2\text{H}_2\text{O}$ ($T_N=4.12$ K) leads to the appearance of a remanent magnetic moment in the substituted compound. Magnetization measurements carried out in single crystals revealed that the remanent magnetization (M_r) appears along the direction of the easy axis when the sample is cooled through the ordering temperature in the presence of an axial magnetic field as low as few millioersts. Samples with $x \sim 0.01$ of Cu and $x=0.008$ of Cd were investigated. The measured magnetization $M=M_r+\chi_{\parallel}H_{\text{axial}}$ observed at applied axial fields $H_{\text{axial}}=0.8$ Oe in both crystals is almost entirely due to the contribution of M_r , since $\chi_{\parallel}H_{\text{axial}}$ is very small. Hysteresis curves were also obtained for the Cd diluted system and the results shows that at $T=1.5$ K a reversal in the direction of M_r is obtained for H_{axial} around 200 Oe. A comparison with previous recent observations in some three-dimensional diluted antiferromagnets is made. © 1996 American Institute of Physics. [S0021-8979(96)18908-X]

The compound $(\text{CH}_3\text{NH}_3)\text{MnCl}_3 \cdot 2\text{H}_2\text{O}$ (MMC) is a quasi-one-dimensional Heisenberg-like antiferromagnet.¹ A three-dimensional ordering of the linear chains occurs at $T_N=4.12$ K. From the value of the spin-flop field at $T=0$ in the magnetic phase diagram a ratio of the anisotropy to the exchange field $H_A/H_E=4 \times 10^{-3}$ was estimated.² In this paper we describe the effects of the substitution of the Mn^{2+} ion by Cu^{2+} and Cd^{2+} in the magnetic properties of this system at low field. We measured the magnetization with a vibrating sample magnetometer (VSM) in the presence of very small axial fields (H_{axial}) provided by a copper solenoid mounted coaxially with the pick-up coils of the VSM.

Figure 1 shows the temperature dependence of the magnetization data for powder samples of MMC with 1% of Cu and 0.8% of Cd (percentages were obtained from relative concentration of the metallic ions in the growing solutions of the crystals). The samples were cooled through T_N in the presence of a magnetic field H_{axial} of 0.8 Oe applied along the axis of the detecting coils. The principal characteristic of the data is the appearance of a spontaneous magnetic moment. This moment is much higher in the Cd substituted compound than in the Cu one. The measured moment can be described by $M=M_r+\chi H_{\text{axial}}$, where M_r is the spontaneous moment and χ is the susceptibility of the compound. In both cases χH_{axial} is much smaller than M_r . Within the resolution of the VSM, no moment was detected in the measurements performed on undiluted ($x=0$) powder samples of MMC. In the Cu doped compound the spontaneous moment develops at a temperature $T=4.5$ K, which is slightly higher than the ordering temperature of pure MMC. In the sample with Cd the moment appears at $T=3.9$ K.

Figure 2 shows the M vs T curves obtained for a single crystal of MMC with 0.8% of Cd. The magnetization was measured along the antiferromagnetic easy axis, in the presence of six different axial fields H_{axial} ranging from 0.08 Oe to 8 Oe which were applied along the easy axis of the crystal. No magnetic moment was detected in measurements made

along a direction perpendicular to the easy axis. Thus, the occurrence of the spontaneous magnetization in the Cd doped crystal is restricted to the direction of the easy axis. This excludes a canting of the antiferromagnetic sublattices as the origin of this effect. At least two important features should be pointed out in the data: (a) the spontaneous magnetization saturates at low axial fields (at 4.8 Oe it is almost saturated in the curves shown in Fig. 2), and (b) there is a region, just below T_N , where the moment appears to be saturated at fields as low as 80 mOe. As for the powder samples the measured magnetization can be described by $M(T)=M_r(T)+\chi_{\parallel}H$, where χ_{\parallel} is the parallel susceptibility. The term $\chi_{\parallel}H$ is here also much smaller than M_r . The saturated value of M_r at 1.5 K is about 0.6% of the value of the

FIG. 1. Temperature dependence of the magnetization of powder samples of MMC with: 0.8% of Cd substitution (○) and 1% of Cu substitution (■). Note the difference in the right-hand scale (for Cu doping) and left-hand scale (for Cd doping).

FIG. 2. Temperature dependence of the magnetization along the easy axis of antiferromagnetic alignment of a crystal of MMC with 0.8% of Cd substitution.

sublattice magnetization of pure MMC. This value is also roughly higher by a factor of 3 than that measured in the corresponding powder sample. No thermal hysteresis were observed in the measurements, e.g., for a given axial field the experimental points obtained during the cooling process and those obtained in the heating process fall into the same M vs T curve.

We observed that once a value of the remanent magnetization is established below T_N the removal of the small axial field has no effects on the value of M_r , e.g., no relaxation effects were detected at these low fields. This behavior was also observed in the measurements made with the powder samples of Cu and Cd doped compounds. The influence of an applied axial field at temperatures below T_N was also investigated. Figure 3 shows the hysteresis cycle obtained at $T=2.5$ K after the sample being cooled in an axial field of 4.0 Oe. Here the external field was provided by a small superconducting coil. Cycles at different temperatures were obtained and the observed behavior for these cycles indicate that at $T=1.5$ K a field of the order of 200 Oe suffices to reverse the remanent magnetization of the sample. This "coercive" field decreases approaching T_N and from the data obtained at 3.77 K we found that a field of ~ 20 Oe is needed in order to reverse the magnetization.

Similar behavior was recently reported in other diluted antiferromagnets.³⁻⁶ In particular, the general features here observed are analogous to those found in the diluted systems $A_2\text{Fe}_{1-x}\text{In}_x\text{Cl}_5 \cdot \text{H}_2\text{O}$ ($A=\text{K}, \text{Rb}$)^{3,4} and $\text{Mn}_{1-x}\text{Zn}_x\text{F}_2$.⁵ These are also low-anisotropy antiferromagnets but with a three-dimensional character. The overall shape of the M vs T curve and the saturation behavior are very similar except for the region near T_N were, as pointed out in the present case, the saturation seems to occur at very low fields. It was shown⁷ that the behavior of the remanent magnetization follows a universal law with a quasilinear behavior in the range $0.25 T_N < T < 0.75 T_N$. Our data seem also to follow this last tendency. Remanent magnetization was also reported in diluted

FIG. 3. Hysteresis cycle of the Cd-substituted crystal at $T=2.5$ K after cooling the sample in an axial field of 4 Oe.

$\text{Fe}_{1-x}\text{Zn}_x\text{F}_2$ ($x=0.54$).⁶ This is a much higher anisotropy system, and the reported data do not show the linearlike trend referred above.

Some previous reports of remanent magnetization in diluted antiferromagnets have been related to an excess magnetization (ΔM) observed between field-cooled (fc) and zero-field-cooled (zfc) procedures, i.e., $\Delta M(T) = M_{fc}(T) - M_{zfc}(T)$.⁸ All these studies were performed at much higher fields (>1000 Oe). They were interpreted in terms of an excess magnetization due to random field (RF) induced domains. This RF induced excess magnetization increases with H^α ($\alpha \geq 2$). The effects here reported occurs at much lower fields and saturates at low fields. This saturation indicates that RF are not the origin of this remanent magnetization. It is an intrinsic characteristics of this disordered system.

Our observations seems to agree well with the formation of a structure of domains in the doped samples of MMC. Each of these domains would carry an excess magnetization at their walls. A field of the order of few Oe applied along the easy axis is sufficient to saturate the excess magnetization. The walls of these domains would be stabilized ("pinned") by the presence of the site disorder introduced by doping.

The high temperature phase of $(\text{Co}_{1-x}\text{Mn}_x)_{65}\text{Ge}_{35}$ is found to be of the hexagonal Ni_2In type in the range of $0 \leq x \leq 0.6$. Co_2Ge is Pauli paramagnetic, and ferromagnetism is induced with substitution of Mn for Co. Magnetization measurement and x-ray diffraction experiments for these compounds have been performed. The x dependences of the Curie temperature T_c and magnetization show a maximum near composition $x=0.25$. X-ray studies show that the lattice constants c are minimum at $x=0.25$. The x dependence of the relative intensities of x-ray lines suggests that the Mn and Co atoms at $2(a)$ sites in the compound $x=0.25$ align alternately in the c direction. The Co atoms at $2(d)$ site and the Ge atoms at $2(c)$ site shift along the c direction are found. The neutron diffraction experiment of $x=0.25$ also support such crystal structure. Maximum of Curie temperature and magnetization of compounds near $x=0.25$ are discussed with the ordering of Mn and Co atoms in the crystal lattice. © 1996 American Institute of Physics. [S0021-8979(96)19008-4]

I. INTRODUCTION

The compound Co_5Ge_3 (Ref. 1) has a hexagonal Ni_2In type structure and shows Pauli paramagnetism. We found that the high temperature phase of the $(\text{Co}_{1-x}\text{Mn}_x)_{65}\text{Ge}_{35}$ system shows a hexagonal structure of the Ni_2In type in the range of $0 \leq x \leq 0.6$. Magnetization measurements show that ferromagnetism is induced with substitution of Mn for Co. The compound CoMnGe (Ref. 2), which is nearly the same as the $x=0.5$ member of this system, is a ferromagnet with a Curie temperature of 265 K.³ Mn and Co atoms occupy the $2(a)$ site and $2(d)$ site, respectively in the crystal lattice shown in Fig. 1 and the magnetic structure is of the collinear type with the spins lying in the basal plane.⁴ Magnetization measurements of $(\text{Co}_{1-x}\text{Mn}_x)_{65}\text{Ge}_{35}$ samples show that the x dependences of the Curie temperature and magnetization have a maximum near the composition $x=0.25$.

FIG. 1. Determined atomic configuration and shift of Co and Ge atoms in the $2(d)$ and $2(c)$ site, respectively. Mn and Co atoms are ordered in $2(a)$ site. The shift in the c direction was estimated to $0.04c$ from x-ray studies.

In order to investigate the crystal and magnetic properties of the $(\text{Co}_{1-x}\text{Mn}_x)_{65}\text{Ge}_{35}$ system ($0 \leq x \leq 0.6$), which is slightly Ge rich from the ideal Ni_2In type, we have made x-ray diffraction experiments, magnetization measurements, and neutron diffraction experiments for $x=0.25$. The maxima of Curie temperature and magnetization of compounds near $x=0.25$ are discussed in terms of the ordering of Mn and Co atoms in the crystal lattice.

II. EXPERIMENTAL PROCEDURE

The polycrystalline $(\text{Co}_{1-x}\text{Mn}_x)_{65}\text{Ge}_{35}$ compounds were prepared from cobalt (99.95% pure), electrolytic manganese (99.94% pure) and germanium (99.999% pure) by arc furnace melting in an argon atmosphere. The melting was repeated several times for homogeneity. The samples were sealed in an evacuated quartz tube with argon gas of 2.2×10^4 Pa, homogenized for more than 170 ks (2 days) at 1073 K, and quenched into water. The crystal structure of powder samples at room temperature was ascertained by x-ray diffraction with $\text{Fe K}\alpha$ radiation. The x-ray diffraction intensity was measured by using the stop count method. Magnetization measurements were made by Faraday type automatic magnetic balance in magnetic fields up to 0.80 MA/m (10 kOe) in the temperature range of 4.2 K and 600 K. Neutron diffraction spectra were taken for $x=0.25$ powder sample at room temperature, using Kinken Powder Neutron Diffractometer (KPD) of Tohoku University installed in the JRR-3M reactor at Japan Atomic Energy Research Institute. The wave length is 1.767 Å. The vacancy concentration of a $x=0.25$ sample was measured by picnometry using CCl_4 .

FIG. 2. Composition x dependences of lattice constants a and c at room temperature. \square of $x=0.5$ is data taken from Ref. 3.

III. RESULTS AND DISCUSSION

The concentration dependences of the lattice constants a and c at room temperature are shown in Fig. 2. Both a and c increase with increasing x . It was found that a contraction of the c axis occurs in the compounds near $x=0.25$ while the a axis changes smoothly with x . The change of unit cell volume with x , calculated from the measured lattice constants a and c is shown in Fig. 3. The contraction of the c axis or unit cell volume may be caused by the ordering of Mn and Co, as is shown later.

The temperature dependence of the magnetization σ for $x=0.1$, $x=0.15$, $x=0.25$, $x=0.4$, $x=0.6$ are shown in Fig. 4. $\text{Co}_{65}\text{Ge}_{35}$ ($x=0$) is a Pauli paramagnet, and ferromagnetism is induced by substitution of Mn for Co. The magnetization σ of all compounds shows a convex curve against temperature except that of $x=0.1$, which shows a concave curve. They are typical of a ferromagnet. For the composition $x=0.25$, the magnetization has a value of $1.09 \mu_B/(\text{Co,Mn})$ at 77 K, and $0.88 \mu_B/(\text{Co,Mn})$ at 295 K.

Figure 5 shows the x dependence of the Curie temperature T_c . The Curie temperature is determined from the intersection of σ_0^2 vs temperature curve and T axis. σ_0 is spontaneous magnetization. T_c shows a maximum near $x=0.25$, i.e., $T_c=412$ K at $x=0.25$. In the case of Ni_2In type ($\text{Co}_{1-x}\text{Fe}_x$)_{1.67} Ge compound,⁵ T_c and σ increase monotonically with increasing x . In the paramagnetic region above the Curie temperature, the reciprocal susceptibility χ^{-1} vs T curve shows good linearity. The x dependence of paramag-

FIG. 3. The composition x dependence of unit cell volume, calculated with the measured lattice constants a and c .

FIG. 4. Temperature dependences of magnetization for the compounds of various composition x in the magnetic field of 9 kOe.

netic Curie temperature Θ obtained from χ^{-1} vs T curve is almost same as the x dependence of T_c although Θ is slightly (~ 10 K) high. The effective magnetic moment μ_{eff} of $4.5 \mu_B/\text{Mn}$ for the compound of $x=0.5$ is obtained from the χ^{-1} vs T curve. This value is slightly larger than $4.05 \mu_B/\text{Mn}$ obtained for CoMnGe by Szytula *et al.*⁴ The cause of the maximum observed in the x dependences of T_c and σ are thought to be due to an ordering of the Mn and Co atoms in the 2(a) site.

In order to investigate the ordering of Mn and Co atoms in the 2(a) site, the x-ray relative intensity $I(001)/I(110)$ was measured. The 001 reflection is a super lattice line that appears due to the ordering of Mn and Co atoms in the 2(a) site as shown in Fig. 1, while the 110 reflection is a fundamental line. The 001 reflection is very weak, so we measured the intensity by means of the stop count method. The x dependence of $I(001)/I(110)$ is shown in Fig. 6. The relative intensity shows a maximum just at $x=0.25$. A shift of atoms along the c direction in the 2(d) and 2(c) sites makes the 001 reflection, but this reflection is small as is obvious from the calculation of x-ray intensity. So the appearance of 001 line is concluded to be the ordering of Mn and Co atoms in the 2(a) site.

The shift of Co and Ge atoms along the c direction in the 2(d) and 2(c) sites is reflected in the remarkable increase of the 104 line intensity and to the decrease of 002, 112, and

FIG. 5. Composition x dependence of the Curie temperature T_c , determined from $\sigma_0^2 - T$ extrapolation.

FIG. 6. Composition x dependence of x-ray relative intensity $I(001)/I(110)$, which is measured by stop count method. The 001 line is the super-lattice line when Mn and Co atoms are ordered in the $2(a)$ site.

114 line intensities. The observed intensity of 104 line of $0.15 \leq x \leq 0.25$ are comparably strong. We have measured the line intensities of $x=0.25$ in order to determine the amount of the shift. The shift in the c direction amounts to $0.04c$ in $x=0.25$ from observed and calculated intensities of these lines, where c is lattice constant.

The vacancy concentration in the $2(d)$ of the compound with $x=0.25$ is estimated from the density measurement by picnometry using CCl_4 . The vacancy concentration amounts to 8.5%. This value is used to calculate the intensity of neutron scattering.

Neutron diffraction experiment was done for the compound of $x=0.25$ at room temperature to get additional crystallographic and magnetic information. The obtained neutron diffraction intensity vs Bragg angle 2θ is shown in Fig. 7(a). The analyzed intensity of the nuclear and magnetic part vs 2θ is shown together with the observed intensity in Fig. 7(b). The condition of calculation is as follows. The shift of Co atoms in $2(d)$ site and Ge in $2(c)$ site along the c direction is used $0.04c$ as determined by x-ray relative intensity. The vacancy concentration used is 8.5% as determined by picnometry. It is assumed that all of the vacancies exist in $2(d)$ site and that the Co and Mn atoms in $2(a)$ site have perfect order. The Debye temperature is determined by fitting the calculated nuclear intensity data to the observed data at higher Bragg angles where the intensity of the magnetic term can be neglect within the experimental error. The fitting is done in a manner as to minimize the $\sum \Delta^2$ where Δ is the difference of calculated intensity and observed one. The determined Debye temperature is 240 K.

The magnetic intensity is calculated with the appropriate Mn and Co moment in the $2(a)$ site and Co moment in the $2(d)$ site but with the total moment to be consistent with the moment obtained from the magnetic measurements. The total intensity (nuclear+magnetic) is also fitted to the observed one so as to minimize the $\sum \Delta'^2$. The analyzed result is that Mn and Co moment in the $2(a)$ site is $(2.8 \pm 0.2) \mu_B$ and $(0.77 \pm 0.2) \mu_B$, respectively and Co moment in the $2(d)$ site is $(0.2 \pm 0.2) \mu_B$ and lying in the basal plane.

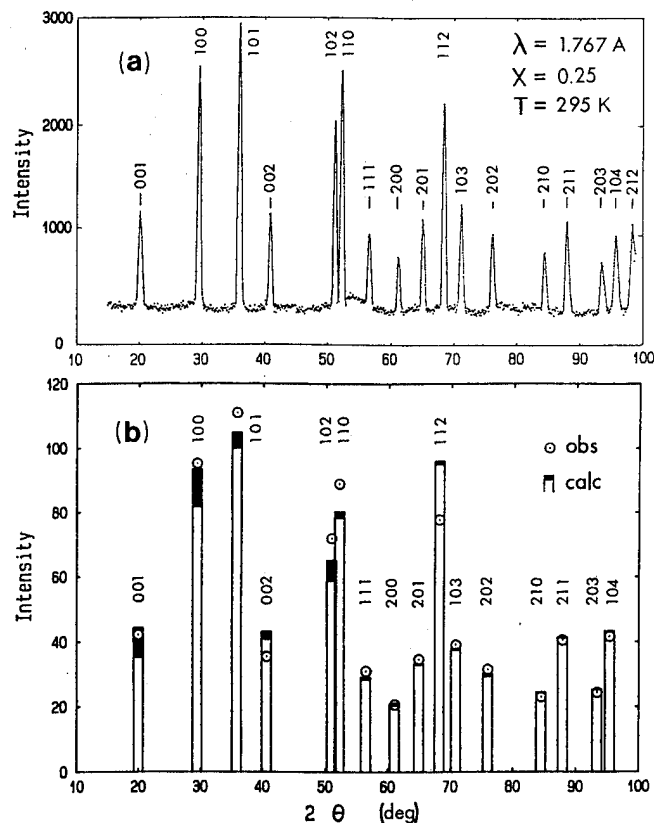

FIG. 7. (a) Powder neutron diffraction spectra for the compound of $x=0.25$ at room temperature. (b) Calculated neutron diffraction intensity for the compound $x=0.25$. The circles are observed intensities and rectangles are calculated ones. See the text for the condition of calculation.

IV. CONCLUSIONS

Ordering of Mn and Co atoms in the $2(a)$ site and a contraction of lattice constant c was found in the compound $(\text{Co}_{1-x}\text{Mn}_x)_{65}\text{Ge}_{35}$ of composition near $x=0.25$ as shown in Fig. 1. Further, the shift of atoms in the $2(d)$ and $2(c)$ sites along the c direction was found.

Maximum of the magnetization and Curie temperature of compound near $x=0.25$ may be caused by contraction of lattice constant c that is induced by the ordering of Mn and Co in the $2(a)$ site, i.e., the shortening of first and second nearest neighbor Co-Mn and third nearest neighbor Co-Co distances is the cause of the maximum. The magnetic interactions J_1 , J_2 , and J_3 are thought to be ferromagnetic.

Magnetism of the solid solution $\text{GdGa}_{1-x}\text{Ge}_x$ (abstract)

A. Leithe-Jasper and K. Hiebl

Institut für Physikalische Chemie, Universität Wien, Währingerstrasse 42, 1090 Wien, Austria

Ternary metal excess rare-earth gallides and germanides have been extensively investigated concerning their interesting physical properties with respect to magnetic and electronic correlations, such as magnetic ordering, intermediate valency, Kondo or heavy fermion behavior. A solid solution of the binary phases GdGa and GdGe was found investigating the phase equilibria in the pseudobinary system Gd-Ga-Ge at $T=800^\circ\text{C}$. Samples with the composition $\text{GdGa}_{1-x}\text{Ge}_x$ ($x=0, 0.1, 0.15, 0.25, 0.5$) were prepared by arc melting the elements under inert atmosphere and subsequent annealing (350 h) in evacuated silica capsules. The crystal structure and unit-cell dimensions were determined by x-ray powder analyses (Guinier technique, $\text{Cu } K\alpha_1$ radiation). Powder patterns were indexed on the basis of a C-centered orthorhombic unit cell. No deviations of the structure type $\alpha\text{-ITI}$ (CrB) have been encountered. A monotonic decrease of the unit-cell volume versus Ge concentration is observed. However, a significant decrease of the b and c parameters is thereby compensated by an increase of the a parameter. Magnetic measurements were performed by SQUID and ac techniques over a temperature range $T=5\text{--}300\text{ K}$ and in external fields up to 6 T. All samples exhibit ferromagnetic order with slightly decreasing T_c as well as values of magnetization (at $T=5\text{ K}$ and $H=0.1\text{ T}$) with increasing concentration x . However, metamagnetic transitions are revealed for all samples with $x>0$. The results are discussed within the concept of indirect exchange interaction (RKKY-type interaction). © 1996 American Institute of Physics.

Neutron scattering and magnetization clouds in dilute Pd based alloys

R. E. Parra and A. C. González

Centro de Física, Instituto Venezolano de Investigaciones Científicas, Apartado 21827, Caracas 1020-A, Venezuela

Neutron scattering data for dilute PdMn, PdCo, and PdFe alloys show forward peaks at small values of K , which indicate an inhomogeneous distribution of the magnetization in these alloys. These inhomogeneities indicate the existence of magnetization clouds that produce the ferromagnetism in these materials; the shape of the peaks at small K also suggest a quasielastic contribution to the neutron diffuse scattering. We, therefore, calculated the neutron scattering cross sections for these alloys using a local moment model; we also developed an analytic expression for the magnetization clouds that can be compared with experimental results. The calculations were made using Monte Carlo methods in the dilute alloy region of impurity concentration. © 1996 American Institute of Physics. [S0021-8979(96)19108-0]

The unpolarized neutron scattering of PdCo, PdMn, and PdFe alloys show large peaks at small values of the wave vector K which would indicate magnetization clouds bigger in magnitude than can be obtained by magnetization measurements.¹⁻³ These results suggest a contribution to the diffuse neutron scattering that cannot be attributed to the magnetization cloud.

Since the pioneering work of Low and Holden,² using neutron scattering to study PdCo and PdFe alloys, many authors have attempted to model theoretically their results. Later, several magnetic measurements, including neutron scattering, were also made on PdMn. In this latter case, there was some uncertainty regarding how much of the giant moment was localized on the impurity. In this work, we present an analysis of the neutron scattering for dilute PdCo, PdFe, and PdMn alloys in order to explain the magnetic characteristics mentioned. We used a local moment model^{4,5} and Monte Carlo simulation methods for this purpose.

We assume that the impurity moment is not affected by its magnetic environment while the moment of host atoms at site n is

$$\mu_n = p_n \mu_i f_i + (1 - p_n) f_h \sum_{m \neq n} \frac{\alpha \mu_i}{\phi_0} \phi_{n-m} p_m, \quad (1)$$

where i refers to an impurity atom and h to a host atom, p_n is a site occupation operator, f is the magnetic form factor, the ϕ 's are magnetic moment perturbations, and α is equal to J_{hh}/J_{ih} , with the J 's being exchange constants. The Fourier transforms of the moments is given by

$$c(1-c)M(K) = \sum_n e^{iK \cdot n} \langle (p_0 - c) \mu_n \rangle, \quad (2)$$

where $M(K)$ is a magnetic moment-site occupation correlation that can be determined by neutron diffuse scattering. For polycrystals, we perform the spherical averages that appear in Eq. (2), and to make the calculations simpler, we introduce the function m_n defined by

$$m_n = \frac{\alpha \mu_i}{\phi_0} \phi_n, \quad (3)$$

which is equal to μ_n for Pd atoms and to $\alpha \mu_i$ for the impurity atom at site 0. By a Fourier transformation this equation gives

$$m(K) = \sum_n m_n e^{iK \cdot n}, \quad (4)$$

which can be solved obtaining

$$m(K) = \frac{\alpha \mu_i}{\phi_0 [1 - \Gamma F_1(K)]}, \quad (5)$$

where Γ is the susceptibility enhancement factor of palladium and $F_1(K)$ is the first-shell structure factor. Doing this we obtain:

$$M(K) = \mu_i f_i + (1 - c) f_h [m(K) - \alpha \mu_i] - c f_h [m(0) - \alpha \mu_i]. \quad (6)$$

This is the general expression that we used to calculate the neutron scattering. In the case of very dilute alloys ($c \rightarrow 0$), we obtain a simpler expression

$$M(K) = \mu_i f_i + f_h [m(K) - \alpha \mu_i]. \quad (7)$$

At $K=0$ we are measuring the total size of the magnetization cloud

$$M(0) = \frac{\alpha \mu_i}{\phi_0 [1 - \Gamma]} + (1 - \alpha) \mu_i, \quad (8)$$

which can be compared with the results obtained by magnetization measurements using the expression

$$M(0) = \frac{d\mu}{dc}, \quad (9)$$

where $\mu = c \mu_i + (1 - c) \mu_h$. From Eq. (8) we can then obtain the parameter α , using the value of the susceptibility enhancement factor $\Gamma = 0.947$ as determined by Medina and Parra⁴ for Pd.

The values of $M(K)$ were calculated using Eq. (6), and were compared with experimental polarized neutron scattering values for dilute PdMn alloys.⁶ The values of μ_{Mn} and of the size of the magnetization cloud, $M(0)$, had to be corrected for antiferromagnetic interactions between Mn pairs.

FIG. 1. Comparison of the calculated polarized neutron scattering values with experimental data (Ref. 6) for PdMn dilute alloys.

If the alloys were totally ferromagnetic we would have a moment of $\mu_{Mn} = 5 \mu_B$, in agreement with an $S_{5/2}$ configuration for Mn, and a value of $M(0) \approx 7.5 \mu_B$ that should agree with Eq. (9). Using the results of Star *et al.*,⁷ we interpolated values of $M(0)$, for these concentrations, to determine the parameter α using Eq. (8). This parameter measures the ferromagnetic interaction host impurity, which we assume to be constant. The new corrected values of $M(0)$ were then calculated using the values of μ_{Mn} obtained by Cable and David⁶ with polarized neutron scattering. We also corrected for atomic short range order (ASRO), using the values obtained by Morgownik *et al.*⁸ for a Pd 9.95 at. % Mn alloy since the ASRO parameters have not been measured for the concentrations studied in this work. Therefore, we assumed, that the ASRO parameters were concentration dependent, i.e., that they are proportional to the values obtained by Morgownik *et al.*, and that the factor of proportionality is $(c_i c_h)/(c_{iM} c_{hM})$, where i and h refer to the impurity and host, respectively, and M refer to the Pd 9.95 at. % Mn alloy. With these values we then calculated $M(K)$ using Eq. (6) and compared them with the polarized neutron scattering data. The results are shown in Fig. 1. The calculation agrees with experimental data for alloys at the lower concentrations; as the concentration is increased there is a small discrepancy at low K .

We also calculated unpolarized neutron scattering and compared it with the experimental data for dilute PdFe, PdCo, and PdMn alloys.^{2,9} We made Monte Carlo calculations using the Hamiltonian

$$H = -\frac{1}{2} \sum_{i,j} J_{ij} S_i \cdot S_j - \sum_i B \cdot S_i, \quad (10)$$

with a field B along the z axis assumed perpendicular to K

FIG. 2. Calculated unpolarized neutron scattering is compared with experimental data (Refs. 2 and 9) for PdFe, PdCo, and PdMn dilute alloys.

and with the conditions that the total magnetic moment keeps its orientation and that the local field is unaffected by the field B .

The quasielastic scattering contribution to the neutron measurements can be calculated using the following formula:

$$T(K) = \frac{1}{(0.27)^2 c(1-c)N} \frac{d\sigma}{d\Omega} = |M(K)|^2 \left\{ \langle (\overline{S^\perp})^2 \rangle + \frac{1}{c(1-c)N} \sum_{ij} e^{iK \cdot (r_i - r_j)} [\langle S_i^\perp \cdot S_j^\perp \rangle - \langle (\overline{S^\perp})^2 \rangle] \right\}. \quad (11)$$

In this expression, $M(K)$ is given by Eq. (6), S_i^\perp is the component of S_i perpendicular to K , the overhead bar indicates spatial averages, and $\langle \rangle$ symbolizes thermal averages.

We then calculated $\langle S_i^z \rangle$, $\langle S_i \cdot S_j \rangle$, and $\langle S_i^z S_j^z \rangle$ from which we obtained the following quantities, needed to calculate $T(K)$ using Eq. (11):

$$\langle S_i^\perp \rangle = \langle S_i^z \rangle \hat{Z}, \quad (12)$$

$$\langle S_i^\perp \cdot S_j^\perp \rangle = \frac{1}{2} \langle S_i^z S_j^z \rangle + \langle S_i \cdot S_j \rangle. \quad (13)$$

The calculations were performed at the temperature of the experiments. The results are shown in Fig. 2. In the case of PdMn, there is a long range contribution that can not be accounted for with this model. On the other hand, the agreement is good for PdFe and PdCo alloys. The calculated scattering shows a strong component of quasielastic scattering due to long range thermal and spatial fluctuations. These long range components of the scattering do not contribute to the magnetization, which is formed by the impurity moment plus all the small moments residing in Pd atoms.

Polarization analysis of the electron spin resonance lines in the $S=1$ one-dimensional antiferromagnet $\text{Ni}(\text{C}_3\text{H}_{10}\text{N}_2)_2\text{NO}_2\text{ClO}_4$

M. Hagiwara and K. Katsumata

The Institute of Physical and Chemical Research (RIKEN), Wako, Saitama 351-01, Japan

The results of electron spin resonance (ESR) measurements on the $S=1$ one-dimensional Heisenberg antiferromagnet $\text{Ni}(\text{C}_3\text{H}_{10}\text{N}_2)_2\text{NO}_2\text{ClO}_4$ (NINO) are reported. We have analyzed the polarization dependence of the ESR transition between the singlet ground state and the first excited triplet which is forbidden for an ordinary Hamiltonian. Our results are consistent with the theory by Sakai and Shiba [J. Phys. Soc. Jpn. **63**, 867 (1994)] proposed to explain the forbidden transition.

© 1996 American Institute of Physics. [S0021-8979(96)19208-7]

One-dimensional Heisenberg antiferromagnets (1DHAFs) have attracted much attention since Haldane conjectured¹ that a 1DHAF with an integer-spin quantum number (S) has an energy gap in the excitation spectrum, while that with a half-odd-integer S has no energy gap. Motivated by this conjecture, a number of experiments have been carried out. The existence of the energy gap in 1DHAFs with $S=1$ was confirmed experimentally by neutron scattering² and magnetization³ measurements. Electron spin resonance (ESR) measurements on 1DHAFs with $S=1$ have unveiled the energy level scheme⁴⁻⁷ and the ground state properties.^{8,9} The first ESR experiment concerning the former topic⁴ on the prototypical $S=1$ 1DHAF compound $\text{Ni}(\text{C}_2\text{H}_8\text{N}_2)_2\text{NO}_2(\text{ClO}_4)$, abbreviated as NENP, exhibited a transition within the first excited triplet. Subsequently, ESR transitions between the singlet ground state at wave vector $k=0$ and the first excited triplet at $k=\pi$, which are forbidden for the ordinary Hamiltonian, have been observed.⁵⁻⁷ A possible mechanism to explain these forbidden transitions has been proposed.^{10,11} Namely, the transverse staggered field caused by the staggered inclination of the principle axis of the g -tensor mixes the eigenstate for $k=0$ with that for $k=\pi$, thus making the transitions between the ground state and the first excited one possible. According to the theory, the transitions occur only for the oscillating magnetic field (H_{rf}) parallel to the external magnetic field (H_0). It is important to perform polarization analysis of the ESR lines to test the validity of this mechanism. In the present paper, we describe the results of ESR measurements on the prototypical $S=1$ 1DHAF compound $\text{Ni}(\text{C}_3\text{H}_{10}\text{N}_2)_2\text{NO}_2(\text{ClO}_4)$, abbreviated as NINO.

First, we summarize the crystal and magnetic properties of NINO. This compound crystallizes in the orthorhombic system and belongs to the $Pbn2_1$ space group.^{12,13} The lattice constants at room temperature are $a=15.384$ Å, $b=10.590$ Å, and $c=8.507$ Å. A schematic view of the crystal structure of NINO is shown in Fig. 1. The Ni^{2+} ions form the chain structure along the b axis via nitrite groups and the chains are well separated from each other by ClO_4 molecules. Since the local environment around Ni^{2+} in NINO is similar to that of NENP, NINO also has a staggered inclination of the principal axis from the chain direction.¹³ The magnetic susceptibilities in a single crystal of NINO along the three crystallographic axes show a hump around 60 K and decrease abruptly when the temperature is decreased

further.¹⁴ No long range ordering has been observed down to 1.5 K.

The single crystal of NINO was grown by a slow evaporation method from an aqueous solution containing the stoichiometric amount of $\text{Ni}(\text{ClO}_4)_2 \cdot 6\text{H}_2\text{O}$, 1,3-propanediamine and NaNO_2 . The dimensions of the sample used in the measurement are 3 mm×3 mm×1.2 mm. The ESR measurement was performed with a spectrometer using a 20 T superconducting solenoid installed in the Institute of Physical and Chemical Research (RIKEN). In order to analyze precisely the polarization dependence of the ESR lines, we made a specially designed resonant cavity operating at around 50 GHz as shown in Fig. 2. The broken lines in Fig. 2 show the rf magnetic field distributions inside the cavity. We measured the two cases where the sample was located at the position designated as A and that designated as B. The external magnetic field was applied parallel to the b axis of the crystal, which was parallel to the z axis in Fig. 2.

Figure 3 shows the derivative signals of the absorption with respect to the magnetic field. The signal at 1.70 T comes from a crystal of iron alum ($\text{FeNH}_4(\text{SO}_4)_2 \cdot 12\text{H}_2\text{O}$) and that at 6.45 T from NINO. We used the ESR signal from iron alum to calibrate the signal intensities from NINO. We obtained the ESR intensity by double integration of the spectrum. When the line shape was asymmetric, a half-part of the signal was used. The ratio of an integrated intensity for the ESR signal from NINO at the position A to that at B is about 1.7 ± 0.1 .

FIG. 1. Schematic view of the crystal structure of NINO.

FIG. 2. A cut view of the resonant cavity used in this experiment. Broken lines show the rf magnetic field distributions inside the cavity.

The signal intensity I for the ESR transition between the ground state $|g\rangle$ and the excited one $|e\rangle$ is, apart from the temperature factor, given by

$$I \propto \int \left[\left| \langle e | \sum_j S_j^z | g \rangle \right|^2 \{H_{\text{rf}}^z(x, y, z)\}^2 + \left| \langle e | \sum_j S_j^x | g \rangle \right|^2 \{H_{\text{rf}}^x(x, y, z)\}^2 + \left| \langle e | \sum_j S_j^y | g \rangle \right|^2 \{H_{\text{rf}}^y(x, y, z)\}^2 \right] dv, \quad (1)$$

where H_{rf}^x , H_{rf}^y , and H_{rf}^z are the x , y , and z components of the rf magnetic field, respectively. According to the theory,¹⁰ $|\langle e | \sum_j S_j^x | g \rangle| = 0$ and $|\langle e | \sum_j S_j^y | g \rangle| = 0$. In this case, the signal intensity is written as

$$I \propto \left| \langle e | \sum_j S_j^z | g \rangle \right|^2 \int \{H_{\text{rf}}^z(x, y, z)\}^2 dv. \quad (2)$$

Here, H_{rf}^z is given by

$$H_{\text{rf}}^z = h \cos \frac{2\pi x}{a} \sin \frac{2\pi z}{d}, \quad (3)$$

where a and d are the dimensions of the cavity in the x and z directions, respectively, and h is a constant. We can calculate the signal intensities I_A and I_B from the NINO sample located at the positions A and B in Fig. 2, respectively. From Eq. (2), the ratio I_A/I_B is given by

$$I_A/I_B = \frac{\int_A \{H_{\text{rf}}^z(x, y, z)\}^2 dv}{\int_B \{H_{\text{rf}}^z(x, y, z)\}^2 dv}. \quad (4)$$

After performing the integration in Eq. (4) within the sample volume, we get $I_A/I_B = 1.75 \pm 0.1$, in good agreement with the observation (1.7 ± 0.1).

Next, we calculate the absolute intensity for the ESR absorption in NINO. For this purpose, we use the ESR signal from Fe alum to calibrate I_A and I_B . Considering the temperature factor, we get $|\langle e | \sum_j S_j^z | g \rangle|^2 \approx 0.03$, which is pro-

FIG. 3. The ESR signal from Fe alum (left) and that from NINO (right) along the b axis obtained at 1.6 K for the frequency of 48 GHz. Here, A and B label the ESR signal from NINO sample located at the positions A and B in Fig. 2, respectively.

portional to the signal intensity according to the theory.¹⁰ We have tried to compare our results with the theory. Although scatter of the data points in the theory is large at low fields, the theory seems to give the right order of magnitude for $|\langle e | \sum_j S_j^z | g \rangle|^2 (0.01)$.

In conclusion, we have made a polarization analysis of the ESR transition between the ground and excited states in NINO. Our results are consistent with the theory by Sakai and Shiba.¹⁰ Clearly, more elaborate calculation of $|\langle e | \sum_j S_j^z | g \rangle|^2$ including the single ion anisotropy terms D and E is needed to get a quantitative agreement between theory and experiment.

We would like to thank Professor H. Shiba and Dr. T. Sakai for helpful discussions. This work was partially supported by the "MR Science Research Program" from RIKEN and by a Grand-in-Aid for Science Research from the Japanese Ministry of Education, Science, Sports and Culture.

Highly crystallized (La,Sr)MnO₃ films deposited by facing targets sputtering apparatus

N. Matsushita, K. Noma, S. Nakagawa, and M. Naoe

Department of Physical Electronics, Tokyo Institute of Technology, 2-12-1 O-okayama, Meguro, Tokyo 152, Japan

La_{1-x}Sr_xMnO₃ films about 4000 Å thick were deposited on thermally oxidized Si wafers, and then their crystalline orientation and magnetic characteristics were investigated. Orientation of (111) in which large ions such as O²⁻, La³⁺, and Sr²⁺ are most closely packed became preferential with increase of total gas pressure P_{total} and partial oxygen pressure P_{O_2} . Although spontaneous magnetization was not detected, even the film deposited at substrate temperature T_s as low as 330 °C revealed obvious orientation of (110) in which metallic ions are most closely packed. The film deposited at T_s of 500 °C, P_{total} of 2.0, and P_{O_2} of 0.1 mTorr, and the film postannealed at 900 °C for 3 h in oxygen atmosphere possessed the saturation magnetization $4\pi M_s$ of 1.2 and 3.5 kG at 77 K and their Curie temperatures were 217 and 313 K, respectively. $B-H$ curves at 77 K revealed that the easy magnetization direction of these films was in-plane. © 1996 American Institute of Physics. I. INTRODUCTION

Perovskite oxides such as (La,Sr)MnO₃ and (La,Bi,Sr)MnO₃ are very attractive material because they possess very interesting properties such as electrical conductivity, ferromagnetism, and magneto-optical Kerr effect. Many researchers have investigated the properties of these bulk materials.^{1,2} The deposition of perovskite films have also been attempted because they seem to be applicable as magnetic layers in the hybrid devices composed of perovskite oxide layers in which YBa₂Cu₃O_{7-y} and BaTiO₃ layers are used as superconductive and ferroelectric components, respectively. However, since these types of oxides exhibit the complicated crystal structure, epitaxial growth substrate such as MgO and SrTiO₃ and high substrate temperature T_s , were necessary for depositing the films with good crystallinity. It had been confirmed in a previous study that the facing target sputtering (FTS) apparatus can achieve "plasma-free" deposition and may be very suitable for depositing the oxide films with excellent crystallinity even at low T_s .³ Therefore, the deposition of La_{1-x}Sr_xMnO₃ films were attempted on amorphous substrate by using FTS apparatus and the dependencies of crystallite orientation and magnetic characteristics on the total and partial oxygen pressure P_{total} and P_{O_2} , respectively, were investigated in this study.

II. EXPERIMENT

All specimen films were deposited by using the facing targets sputtering (FTS) apparatus.

A pair of targets with the same composition of La_{0.76}Sr_{0.24}Mn_{0.78}O_{3-y} were prepared by a dry ceramic technique. They were presintered from the starting mixture of La₂O₃, SrCO₃, and MnO₂ powder at 1000 °C for 1 h and

1100 °C for 1 h and finally sintered at 1200 °C for 4 h. Sintered targets possessed the saturation magnetization M_s of 38.5 emu/g and it was smaller than 40% of M_s of a perfect single crystal with the same composition (about 100 emu/g).⁵

In this FTS system, the vacuum chamber was evacuated by the diffusion pump and the average background pressure was 8.7×10^{-7} Torr. Total and oxygen gas pressure P_{total} and P_{O_2} were in the range of 1.0–4.0 and 0.0–0.4 mTorr, respectively. The Si plates with thermalized surface layer (SiO₂/Si wafers) were used as substrates. The substrate temperature T_s was in the range of 330–600 °C. Film thickness could be controlled by adjusting deposition conditions and the specimen films about 4000 Å thick were for deposited at T_s of 500 °C and at P_{total} and P_{O_2} of 2.0 and 0.1 mTorr, respectively.

The dc current supply was used for sputtering and it was set at a constant value of 0.2 A. The discharge voltage depended on P_{total} and P_{O_2} , and it was in the range from 240 to 330 V.

Film composition was analyzed by the induced coupled plasma spectroscopy (ICPS). Crystallite orientation was evaluated on the x-ray diffraction (XRD) diagram and saturation magnetization was measured by using the vibrating sample magnetometer (VSM).

III. RESULTS AND DISCUSSIONS

A. Film composition

When the targets with stoichiometric composition of La_{0.76}Sr_{0.24}Mn_{1.0}O_{3-y} were sputtered, Mn content x was higher than 1.0 in the film composition represented as La_{0.76}Sr_{0.24}Mn _{x} O_{3-y}. Therefore, targets with lower x of 0.78, i.e., composition of La_{0.76}Sr_{0.24}Mn_{0.78}O_{3-y} were used and

FIG. 1. XRD diagrams of films deposited at various P_{O_2} .

then x in the film composition was 0.97, of which the value seemed to be almost the same as x of 1.0 corresponding to stoichiometric composition.

B. Crystallite orientation

Figure 1 shows the XRD diagrams at various P_{O_2} for the films deposited at T_s of 500 °C and P_{total} of 2.0 mTorr. The ratio in peak height $I_{(111)}/(I_{(110)} + I_{(111)})$ increased with an increase of P_{O_2} as shown in Fig. 2. The (110) peak is the highest in the powder x-ray diffraction diagram and (110) corresponds to the most closely packed plane of metallic ions of La^{3+} , Sr^{2+} , Mn^{3+} , and Mn^{4+} as shown in Fig. 3(a). On the other hand, (111) corresponds to the most closely packed plane of large ions of La^{3+} , Sr^{2+} , and O^{2-} as shown in Fig. 3(b). It seemed to be difficult to deposit the films with sufficient (111) orientation by any conventional sputtering methods, because the oriented plane which is mainly composed of very light O ions would be destroyed by the heavy bombardment of γ -electrons and negative ions. On the other hand, it

FIG. 2. P_{O_2} dependences of ratio in peak height $I_{(111)}/(I_{(110)} + I_{(111)})$. (The indicated solid curve is intended as a guide to the eye for the reader.)

FIG. 3. Schematic illustration of (a) (110) plane and (b) (111) plane in $(La,Sr)MnO_3$ unit cell.

has been confirmed that FTS system can easily deposit the films with excellent orientation of the most closely packed plane (111) of oxygen ions on the “plasma-free” substrates, when enough amount of oxygen gas exists around the growing film surface.

Figure 4 shows the XRD diagrams for the films deposited at P_{total} of 1.0, 2.0, and 4.0 mTorr. Although the preferential orientation plane was (111) at P_{total} of 1.0 mTorr, it changed to (110) at P_{total} of 4.0 mTorr and the ratio in peak heights were almost the same as that in the x-ray diagram of $(La,Sr)MnO_3$ powder.⁴ Since the kinetic energy of sputtered particles decreased with an increase of P_{total} and since the increase of P_{total} correspond to the decrease of mobility of oxygen atoms on the substrate plane, the peak height of (111) seemed to decrease with increase of P_{total} .

Highly crystallized film was deposited even at low T_s of 330 °C and then the preferential orientation plane was (110) as shown in Fig. 5. Since T_s was low enough even for the Sr atom, which has high vapor pressure at 500 °C, the preferential orientation of (110), i.e., the most closely packed plane of metallic ions, was clearly observed. However, since the

FIG. 4. XRD diagrams of films deposited at various P_{total} .

FIG. 5. XRD diagram of film deposited at low T_s of 330 °C.

crystallites did not fully grow at T_s of 330 °C, spontaneous magnetization was not detected even at low measurement temperature of 77 K.

C. Magnetic characteristics

Magnetic characteristics were investigated for the as-deposited films at T_s of 500 °C, P_{total} of 2.0 mTorr and

FIG. 6. In-plane(//) and perpendicular(⊥) B - H loops of as-deposited and postannealed films at 77 K.

FIG. 7. Temperature dependences of saturation magnetization $4\pi M_s$ of as-deposited and postannealed films.

P_{O_2} of 0.05–0.4 mTorr and for the films postheated at the annealing temperature T_A of 900 °C for 3 h in oxygen gas. The as-deposited films possessed very small saturation magnetization $4\pi M_s$ at room temperature and the maximum value of $4\pi M_s$ was 0.24 kG at P_{O_2} of 0.1 mTorr. The annealing treatment increased $4\pi M_s$ for all films deposited at any P_{O_2} . Although the films deposited at P_{O_2} of 0.1 mTorr took the maximum value of 0.47 kG, it was fairly smaller than that of the bulk with same composition (about 5.0 kG).

Therefore, B - H loops of the as-deposited and the postannealed films were measured at 77 K in in-plane(//) and perpendicular(⊥) direction, respectively, as shown in Figs. 6(a) and 6(b). Since B - H (//) was saturated and B - H (⊥) was not saturated at the applied field of 1 kOe, it was clear that their easy magnetization direction was in-plane, while the coercivities $H_{c\parallel}$ and $H_{c\perp}$ were not so different. It seemed that, since the crystallinity was improved by annealing the films in oxygen atmosphere, larger $4\pi M_s$ and higher H_c were obtained. Since the lack of oxygen ions causes the change of spin arrangement from parallel to antiparallel, the as-deposited film possessed smaller $4\pi M_s$ than the postannealed one. However, the $4\pi M_s$ of the postannealed film took the maximum value of 3.5 kG, which was smaller than that of the bulk. Figure 7 shows the temperature dependencies of $4\pi M_s$ of as-deposited and the postannealed films. They seemed to possess larger $4\pi M_s$ at a temperature below 77 K. The Curie temperatures T_C were 217 and 313 K, respectively, while T_C of the bulk $\text{La}_{0.67}\text{Sr}_{0.33}\text{Mn}_{1.0}\text{O}_3$ was about 360 K. It seemed that, since crystallites did not fully grow up and the oxygen content was insufficient even in the postannealed film, it exhibited lower T_C and smaller $4\pi M_s$ than the bulk.

α'' -Fe₁₆N₂ phase epitaxially grown by sputter beam method

Satoshi Okamoto, Osamu Kitakami, and Yutaka Shimada

Research Institute for Scientific Measurements, Tohoku University, Sendai 980-77, Japan

Epitaxial Fe-N films have been grown on Fe or Ag (001) single-crystal underlayers by the sputter beam method. The Fe-N films on both underlayers have a bct structure (α' -martensite), whose lattice is elongated along the [001] direction by nitrogen atoms located in octahedral interstices of α -Fe. These films possess well-defined crystal orientation and exhibit a higher saturation magnetization ($4\pi M_s$) than that of α -Fe for a certain range of various nitrogen content. Postannealing promotes ordering of nitrogen atoms in the bct lattice, resulting in precipitation of a metastable α'' -Fe₁₆N₂ phase in Fe-N films. The $4\pi M_s$ of the annealed samples tends to increase with the increase of the α'' volume fraction, and the Fe-N film with $4\pi M_s$ of about 25 kG contains 26–33 vol% α'' phase. While both Fe and Ag underlayers can promote epitaxial growth of the Fe-N films, very fast ordering of nitrogen atoms and easily decomposed α'' -Fe₁₆N₂ have been observed in the sample on a Ag underlayer. This fact leads to the fact that the ordering rate and the stability of α'' -Fe₁₆N₂ are very sensitive to its crystal quality. © 1996 American Institute of Physics. [S0021-8979(96)41308-X]

I. INTRODUCTION

Since the discovery of an abnormally high magnetization (28.3 kG) in α'' -Fe₁₆N₂ by Kim and Takahashi,¹ a lot of intensive work has been done to clarify the physical properties of α'' -Fe₁₆N₂. However there have been many controversial results on the magnetic properties of the α'' -Fe₁₆N₂. The reported values of the saturation magnetization ($4\pi M_s$) range from about 30 kG^{2,3} or 25–28 kG^{4–7} to almost the same for α -Fe.⁸ A crucial discrepancy has also been seen in the Mössbauer spectra of the α'' -Fe₁₆N₂. Most reports insist that the three different hyperfine fields correspond to three Fe sites in the α'' -Fe₁₆N₂.^{4,8,9} In contrast, Sugita *et al.* have recently confirmed that there is only one hyperfine field in the α'' -Fe₁₆N₂ single-crystal film.²

We consider that such a contradiction was mainly caused by inappropriate structural characterization of the Fe-N samples. Usually, the structural analysis of Fe-N samples is performed by the conventional x-ray diffraction (XRD) method. As was pointed out in the previous paper,¹⁰ improper conclusions will be derived unless very careful corrections are performed.

In the present study, Fe-N films are epitaxially grown on Fe or Ag (001) underlayers by the sputter beam (SB) method by which high quality single-crystal films have been fabricated,¹¹ and their structures are carefully determined. We will show the relationship between the magnetization and some structural factors of the Fe-N films on Fe and Ag underlayers.

II. EXPERIMENT

Figure 1 shows a schematic diagram of the SB system. This system consists of a discharge chamber and a film deposition chamber.¹¹ GaAs (001) single-crystal wafers were used as substrates. Prior to film deposition, the SB system was evacuated to 3×10^{-7} Torr for the discharge chamber and 3×10^{-8} Torr for the deposition chamber.

Fe underlayers were deposited directly onto GaAs substrates, while Ag underlayers were deposited on 30-Å-thick Fe seed layers. The substrate temperature (T_s) was 250 °C

with an Ar gas pressure (P_{Ar}) of 4 mTorr in the discharge chamber and 0.1 mTorr in the deposition chamber. Fe-N films were deposited at T_s =room temperature (rt) with P_{Ar} =4 mTorr in the discharge chamber and N₂ partial pressure (P_N)=0.1–0.35 mTorr in the deposition chamber. The final forms of the prepared samples are Fe-N (800 Å)/Fe (400 Å)/GaAs (001) and Fe-N (1200 Å)/Ag (500 Å)/Fe (30 Å)/GaAs (001). The deposition rate was controlled to be 4–4.2 Å/min throughout the experiments. Bias voltage (V_b) of –20 V was applied to the substrate during the deposition of the Fe-N films in order to enhance epitaxial growth of the films by Ar ion bombardment.¹² In the present experimental conditions, the kinetic energy of the ions is about –17 eV which is an optimum value for epitaxial growth of

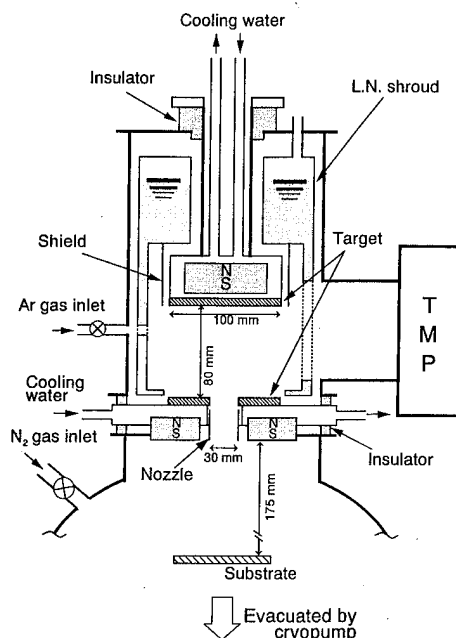

FIG. 1. The schematic of the sputter beam system.

FIG. 2. RHEED patterns from [110] direction of the (a) Fe underlayer, (b) Fe-N film on Fe underlayer, (c) Ag underlayer, and (d) Fe-N film on Ag underlayer.

Fe-N film.¹⁰ Annealing of the films was sequentially carried out at a temperature (T_a) of 200 °C for 10–100 h. The crystal structures of the films were investigated by an x-ray diffractometer (using Cu K α line) which has a focusing length of 185 mm, and their surface structures were investigated by the reflection high-energy electron diffraction (RHEED). The value of $4\pi M_s$ was measured by a vibrating sample magnetometer (VSM) with an applied field of 15 kOe. The $4\pi M_s$ of our α -Fe single-crystal films was within 21.5 ± 0.5 kG.

III. RESULTS AND DISCUSSION

Figure 2 shows the RHEED patterns of the Fe-N films grown on Fe and Ag underlayers. The diffraction from the two underlayers shows very sharp streaks, indicating that they are epitaxially grown and possess very flat surfaces. We note that the Fe-N films on those underlayers also exhibit continuous streaks reflecting the symmetry of the underlayers although the streaks become a little obscure. The crystal quality of the Fe-N film on the Ag underlayer is found to be somewhat inferior to that on the Fe underlayer. From the RHEED and XRD measurements, the crystal structure of those Fe-N films is obviously the disordered phase (α' -martensite). According to the rocking curve measurements, the dispersion angle of the Fe and Ag (002) peak is smaller than 1° and that of α' -Fe-N (002) peak is less than 2°.

The RHEED patterns of the annealed Fe-N films are shown in Fig. 3. The streaks with a half period of the original ones appear and become clearer as the annealing time increases. These streaks indicate formation of the ordered phase (α'' -Fe₁₆N₂). For the sample annealed for 100 h, the streaks with the half period are very strong but with rather spotty diffraction, indicating that clusterlike α'' phase precipitates in the Fe-N film. As is clear in the RHEED pattern of the sample annealed for 30 h, more rapid ordering of N sites is found in the sample on the Ag underlayer. Too prolonged annealing, however, reduces the diffraction intensity of the ordered phase. From this result, it is clear that the ordering of N atoms is related to the morphology of Fe-N

FIG. 3. Change of RHEED patterns of Fe-N films with the annealing time. (a)–(c) are those on Fe underlayer and (d)–(f) are those on Ag underlayer.

films. Since surface energy of Ag is extremely small compared with that of Fe, the Fe-N film on the Ag underlayer may take the form of the so-called island structure, resulting in a higher density of defects and grain boundaries. Hence, the N atoms in the Fe-N film will easily move to the ordered sites of α'' -Fe₁₆N₂ through diffusion through the lattice defect or grain boundary.

Figure 4 shows the XRD profiles of the annealed Fe-N

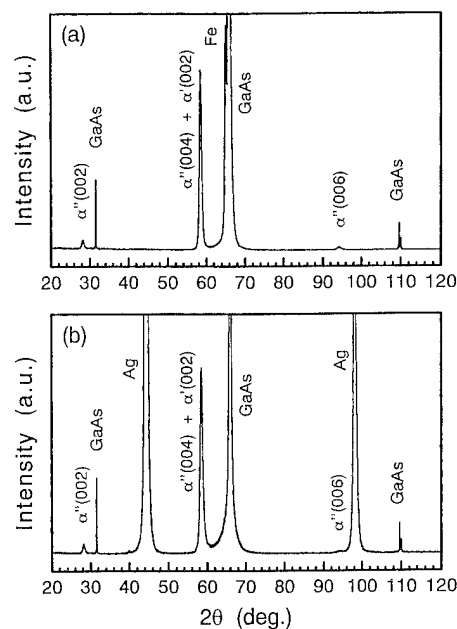

FIG. 4. Typical XRD profiles of annealed Fe-N films on (a) Fe underlayer and (b) Ag underlayer.

FIG. 5. Saturation magnetization $4\pi M_s$ of Fe-N films on Fe and Ag underlayers as a function of the unit cell volume of α' -martensite.

films. Both the Fe-N films on Fe and Ag underlayers exhibit the distinct diffraction peaks from $\alpha''(002)$ and $\alpha''(006)$, and these peaks are evidence of the existence of α'' -Fe₁₆N₂. In addition to (002) and (006) peaks, we have observed the peculiar peaks of (103), (105), (204), and (114) from α'' -Fe₁₆N₂ by asymmetric XRD measurements.¹⁰ For both Fe and Ag underlayers, the lattice constants a and c of α'' -Fe₁₆N₂, respectively, are 5.70–5.71 and 6.30–6.31 Å, which are very close to the values reported by Jack ($a=5.72$ Å and $c=6.29$ Å)¹³ and so the bct structure of our α'' -Fe₁₆N₂ is slightly expanded to the c -axis direction.

Figure 5 shows the dependence of $4\pi M_s$ on the unit cell volume of α' phase. It has been found to be proportional to the nitrogen content in the Fe-N film.¹² $4\pi M_s$ of α' phase on both Fe and Ag underlayers are obviously larger than that of Fe for all N content range examined in this experiment. The maximum value of $4\pi M_s$ of α' phase is 23.3 kG. However, $4\pi M_s$ tends to decrease to the value of α -Fe as α' unit cell expands further in the high N content region. This decrease may be attributed to existence of nonmagnetic phase (γ -austenite) or the other unknown reason. The Mössbauer measurement is in preparation in order to explain this change.

In Fig. 6, $4\pi M_s$ of Fe-N films are shown as a function of the α'' phase volume fraction. The α'' volume fraction was determined from x-ray diffraction intensity ratio $I_{\alpha''(002)}/I_{[\alpha''(004)+\alpha'(002)]}$ with the theoretical intensity ratio $I_{\alpha''(002)}/I_{\alpha''(004)}$ of α'' -Fe₁₆N₂. The theoretical ratio was determined with exact evaluation of the line absorption factor and irradiation area of the x-ray beam. As seen in this figure, $4\pi M_s$ of the annealed films tends to increase from 23 kG to about 25 kG with increasing the fraction of the α'' -Fe₁₆N₂. This result demonstrates that α'' -Fe₁₆N₂ obviously has a very high magnetization. It is, however, difficult to accurately determine the $4\pi M_s$ of α'' -Fe₁₆N₂ because of the limited α'' volume fraction, and as is noted in Fig. 5, $4\pi M_s$ of α' -martensite cannot be fixed.

IV. CONCLUSIONS

Fe-N (001) epitaxial films were grown on Fe and Ag (001) single-crystal underlayers by the SB method, and

FIG. 6. Saturation magnetization $4\pi M_s$ of Fe-N films on Fe and Ag underlayers as a function of the volume fraction of α'' -Fe₁₆N₂.

α'' -Fe₁₆N₂ phase was precipitated in the films by post annealing. The epitaxially grown Fe-N (001) film, whose structure is bct α' -martensite, possesses a saturation magnetization larger than that of α -Fe. Formation of α'' -Fe₁₆N₂ was clearly observed in the films annealed at 200 °C. The magnetization of the annealed Fe-N films tends to increase with increasing the volume fraction of the α'' -Fe₁₆N₂. This result indicates that the α'' -Fe₁₆N₂ has a magnetization much larger than α -Fe. But the magnetization of α'' -Fe₁₆N₂ cannot be accurately determined in this study. We are now preparing Mössbauer measurements in order to determine the magnetization of α'' -Fe₁₆N₂ and α' -martensite in our Fe-N film.

We did not find out any distinct differences in the magnetic properties and the crystal structures of the Fe-N films on Fe and Ag underlayers. However, the ordering of N atoms is more rapid in the α' -martensite on the Ag underlayer than that on the Fe underlayer, moreover, too long annealing made α'' -Fe₁₆N₂ easily decompose in the samples on the Ag underlayer. That the morphology of the Fe-N films may affect the ordering rate and the stability of α'' -Fe₁₆N₂. The lattice defect or grain boundary may accelerate ordering of N atoms in the α' -martensite, but may also impede the thermal stability of ordered N atoms in α'' -Fe₁₆N₂.

The formation of stable Co/Co₂MnSn two phase magnets

T. W. Kim and R. J. Gambino

Department of Materials Science and Engineering, SUNY at Stony Brook, New York 11794

The phase equilibria in the system Co–Mn–Sn have been studied with compositions along the join Co–CoMnSn. This is part of an effort to form a macroscopic ferrimagnet with two metallic ferromagnetic phases, Co and Co₂MnSn. As-cast arc melted alloys have been made with Co compositions from 33 to 78 at. %. Three different phase and magnetization regions are observed with increasing Co composition. Cobalt becomes the primary phase at more than 71 at. % Co and crystallizes out of a Co₂MnSn rich matrix. It is shown from x-ray diffraction analysis and the T_c change with Co compositions that the Co phase in Co₂MnSn matrix is probably a Co–Mn solid solution. From the break in the magnetization vs temperature curves of two phase magnets with two different compositions, Curie temperatures are determined as approximately 160 °C and 175 °C for the Co–Mn solid solution phase. The exchange coupling at phase boundary is proposed by the analysis of coercivity vs temperature data. © 1996 American Institute of Physics. [S0021-8979(96)27908-1]

INTRODUCTION

Macroscopic ferrimagnets consist of two phases in intimate contact which exchange couple ferrimagnetically. Previous work on Co–EuS films which consist of about 10 nm particles of EuS have shown that macroscopic ferrimagnets can have unusual magneto-optical¹ and magneto-transport² properties. The EuS is exchange coupled antiferromagnetically to the cobalt at least at the Co/EuS interface. In the Co–EuS system, the Co matrix is a conductor but the EuS in the precipitate particles is a semiconductor. Even though the resistivity change of this system is large, the magnetoresistance is small because of the high resistivity of a large volume fraction of semiconducting phase.³

For this reason, we are investigating phase equilibria in a system containing two metallic ferromagnetic phases, Co and Co₂MnSn. We have found that in the Co/Co₂MnSn system the two metallic phases are a low T_c and low magnetization phase, hexagonal Co solid solution, and a high T_c and high magnetization phase, Co₂MnSn. Microstructure shows a Co solid solution precipitates in the Co₂MnSn Heusler alloy matrix, which may be crystallographically coherent with the matrix.

EXPERIMENTAL METHODS

Ingots were prepared by arc melting in a commercial arc furnace with a water cooled hearth and a water cooled tungsten electrode. The chamber was evacuated by a mechanical pump and back filled with argon several times. The high purity argon gas (99.999%) flowed through the chamber continuously during arc melting. The analysis of microstructures was made with backscattered electron image on a scanning electron microscope (SEM) because optical microscope did not provide enough contrast to analyze the Co precipitates in Co₂MnSn Heusler alloy. The composition analysis of the phases was carried out with energy-dispersive analysis of x rays (EDAX). The samples with two phases were characterized by x-ray diffraction analysis. Magnetization loops and magnetization vs temperature were made using a vibrating sample magnetometer (VSM) with a temperature controlling system.

RESULTS AND DISCUSSION

There are three different phases, Fig. 1, and three magnetization regions, Fig. 2, with composition along the join Co–CoMnSn. At 33–50 at. % Co, Co–Mn–Sn phase is surrounded by paramagnetic Sn-rich phase, Fig. 1(a). The magnetizations in this region are relatively small compared to other two phase regions. Figure 1(b) shows that Co₂MnSn Heusler alloy with 50 at. % of Co is formed as a single phase. At 50–71 at. % Co, Co particles precipitate along the columnar boundary which surround Co₂MnSn [Co₃MnSn; Fig. 1(c)], and with increasing Co, Co particles start to precipitate in Co₂MnSn matrix [Co₄MnSn; Fig. 1(d)]. The magnetization of Co₂MnSn is large and increases with Co con-

FIG. 1. SEM backscattered electron images of polished sections of ingots; (a) CoMnSn (33 at. % Co), (b) Co₂MnSn (50 at. % Co), (c) Co₃MnSn (60 at. % Co), (d) Co₄MnSn (67 at. % Co), (e) Co₅MnSn (71 at. % Co), (f) Co₇MnSn (78 at. % Co).

FIG. 2. (a) Magnetization, (b) coercivity and I_r/I_s as a function of Co composition along the join Co–CoMnSn.

centration. Cobalt becomes the primary phase at more than 71 at. % Co [Co_5MnSn ; Fig. 1(e)] and crystallizes out of a Co_2MnSn rich matrix. The remanence and coercivity suddenly increase at this composition [Fig. 2(b)]. Even though Co concentration increases, magnetization decreases, then increases again in this Co composition range but the change of magnetization is small. The change of remanence is also small. The volume fraction of Co phase increases with Co composition [Co_7MnSn ; Fig. 1(f)]. The x-ray diffraction pattern from the Co_7MnSn composition shows two phases. Comparing with the peaks from arc-melted pure Co and single phase Co_2MnSn Heusler alloy, the diffraction peaks of Co_7MnSn match with those of hexagonal Co and Co_2MnSn Heusler alloy. All peaks from hexagonal Co are shifted in this sample. The peaks from Co_2MnSn with typical Heusler alloy structure are not shifted. New lattice parameters were calculated using the diffraction angles of (100) and (002) peaks of hexagonal Co. The c axis increases 2.2% to 4.17 Å and the a axis decreases 2.3% to 2.45 Å. On the basis of these new lattice parameters, the diffraction angles of other hexagonal Co peaks were calculated. These calculated angles are compatible with the observed hexagonal Co peaks in the two phase magnet. From the overlap of hexagonal Co and Co_2MnSn peaks and the shift of the hexagonal Co peaks, it is possible that the Co phase and Co_2MnSn Heusler alloy phase are crystallographically coherent. The intensities of (200), (222), (420) reflections of Co_2MnSn Heusler alloy are significantly small, indicating that Mn and Sn in the structure of Co_2MnSn phase are disordered.⁴

The saturation magnetization, M (emu/cm³), vs volume fraction of Co to Co_2MnSn is shown in Fig. 3. Line *a* is the calculated magnetization based on volume fractions of Co and Co_2MnSn and the magnetization in line *b* comes from experimental data. The volume fraction was calculated assuming that Co and Co_2MnSn have their normal crystalline densities.

The magnetization and coercivity vs temperature on Co_6MnSn and Co_7MnSn compositions which have more vol-

FIG. 3. Saturation magnetization, M_s (emu/cm³), as a function of volume fraction of Co to Co_2MnSn ; (a) theoretical magnetization, (b) experimental magnetization.

ume fraction of Co are shown in Fig. 4(a) and Fig. 4(b), respectively. The phase transformation from hexagonal Co to fcc Co takes place at around 430 °C.⁵ Therefore, this experiment was carried out at –150–400 °C temperature range. By extrapolating high-temperature data, T_c of the lower T_c phase can be estimated. Figure 4(a) shows that these samples contain two phases: one with low T_c and low magnetization and the other with high T_c and higher magnetization. By extrapolating the two curves of Co_6MnSn and Co_7MnSn to

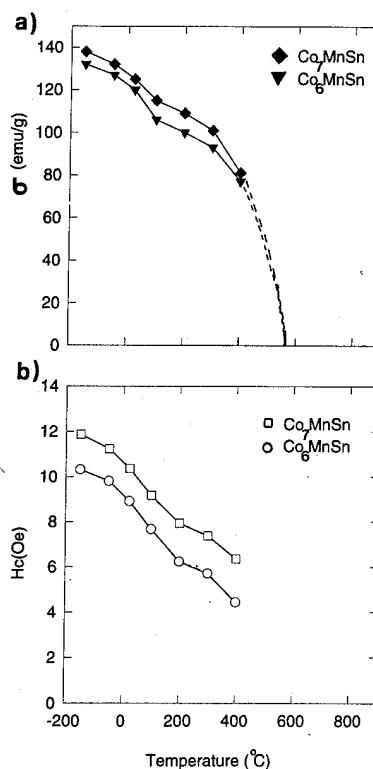

FIG. 4. (a) Magnetization vs temperature, and (b) coercivity vs temperature curves of the Co_6MnSn and Co_7MnSn samples with stable Co/ Co_2MnSn two phases.

high temperature, the curves merge on the temperature axis. The temperature at this point is approximately 570 °C consistent with T_c , 556 °C, of Co_2MnSn of Heusler alloy. The T_c of the hexagonal Co solid solution can be estimated by extrapolating from the break in the magnetization curve [Fig. 4(a)]. The Curie temperatures of the Co–Mn solid solution in the Co_6MnSn and Co_7MnSn samples are approximately 160 °C and 175 °C, respectively. The increase of Mn concentration lower T_c , which is evidence of Co–Mn solid solution.

Figure 4(b) shows the coercivity in Co_6MnSn and Co_7MnSn samples as a function of temperature. The coercivity change with temperature can be divided as two regions with about 150 °C in the center as the case of magnetization vs temperature. The coercivity at $T < 150$ °C is that of the Co phase. The Curie temperatures determined from the temperature at which $H_c(T)$ changes slope is about 180 °C in approximate agreement with the T_c from magnetization vs temperature [Fig. 4(a)]. The single phase Co_2MnSn Heusler alloy shows a closed loop without coercivity or remanence. In Fig. 4(a), however, there is extra coercivity at $T > 150$ °C where the Co_2MnSn phase is the only magnetic phase. This

suggests that the extra coercivity at $T > 150$ °C is associated with exchange coupling of Co and Co_2MnSn Heusler phase at the phase boundary.

CONCLUSIONS

Stable Co/ Co_2MnSn two phase magnet consisting of metastable Co precipitates in Co_2MnSn Heusler alloy matrix is formed at composition >71 at. % of Co. Both phases may be crystallographically coherent. The extra coercivity at $T > 150$ °C and the Co composition dependence of Curie temperature probably indicate that there is the exchange coupling at phase boundary. It can be expected that the exchange coupling will be increased by forming the very small particles through rapid quenching methods or thin film technology because of the increased surface to volume ratio.

Magnetic phase transitions in $\text{RENi}_2\text{B}_2\text{C}$ ($\text{RE}=\text{Ho}, \text{Dy}, \text{Tb}$) studied by ^{57}Fe Mössbauer spectroscopy (abstract)

D. Sánchez, H. Micklitz,^{a)} M. B. Fontes, S. L. Bud'ko, and E. Baggio-Saitovitch
Centro Brasileiro de Pesquisas Físicas, Rua Xavier Sigaud 150, Urca, Rio de Janeiro, Brazil

The rare earth (RE) nickel borocarbides are intermetallic layered compounds which offer the possibility to study the interplay between superconductivity and magnetism. We have doped $\text{RENi}_2\text{B}_2\text{C}$ ($\text{RE}=\text{Ho}, \text{Dy}, \text{Tb}$) with ~ 1 at. % ^{57}Fe in order to study the magnetic phase transitions occurring in these systems by a local probe, i.e., by ^{57}Fe Mössbauer spectroscopy. Sample characterization by x-ray diffraction as well as ac susceptibility measurements showed mainly single phase. The room temperature and 4.2 K ^{57}Fe ME spectra essentially show one quadrupole doublet ($\Delta \sim 0.20$ mm/s) for all compounds, except for $\text{RE}=\text{Tb}$.¹ A magnetic hyperfine (hf) field appears in the case of $\text{RE}=\text{Tb}$ and Ho at $T_N \sim 15$ and 8 K, respectively. The magnetic hf field for Tb at 4.2 K is $B_{\text{hf}}=0.86$ T, while it is quite smaller for Ho [$B_{\text{hf}}(5\text{ K}) \sim 0.30$ T]. Since ^{57}Fe at the Ni sites in $\text{RENi}_2\text{B}_2\text{C}$ does not have its own magnetic moment, all magnetic hf fields are resulting from the neighboring RE moments.¹ The absence of a hf field in $\text{DyNi}_2\text{B}_2\text{C}$ at 4.2 K confirms the results from neutrons diffraction experiments:² the magnetically ordered state in these two compounds is a simple collinear antiferromagnet. For Tb and Ho, however, the spin structure in the magnetically ordered state is not collinear, resulting in a transferred magnetic hf field at the ^{57}Fe nucleus. © 1996 American Institute of Physics. Morin-like spin reorientation in BiPb-2201 ferrates with iron in octahedral oxygen coordination

M. Rosenberg and Th. Sinnemann

Experimentalphysik VI, Ruhr-Universität Bochum, 44780 Bochum, Germany

Institute of Physics & Technology of Materials, P.O. Box MG 76900 Bucharest, Romania

S. Kemmler-Sack

Institut für Anorganische Chemie, Universität Tübingen, 72076 Tübingen, Germany

From a Mössbauer spectroscopy study of the BiPbSrCaFe_{6+z} ferrate, prepared under different conditions, strong evidence for a variety of Morin-like spin-reorientation processes similar to the ones occurring in hematite was found. The phase evolution, their energetical and dynamical Mössbauer parameters as well as the spin-rotational process are described in detail and finally correlated with a proposed mechanism. © 1996 American Institute of Physics. [S0021-8979(96)09008-0]

The mechanism of the Morin spin reorientation occurring in hematite is based on the interplay of the two types of anisotropies of the iron ions, i.e., the single-ion anisotropy which gives rise to a preference for an axial orientation of the Fe magnetic moments and the anisotropy of the magnetic dipole-dipole interaction which makes a planar spin orientation more favorable. It is worth mentioning that according to the theoretical study of Artman *et al.*¹ the two opposite contributions to the anisotropy energy differ only slightly in magnitude (about 2%), but the single-ion component predominating at low temperature gives rise to the orientation of the iron spins along the trigonal axis. Because of the slight difference in the temperature dependence of the two types of anisotropy energies, the dipolar magnetic energy becomes larger around 260 K giving rise to the Morin spin reorientation and therefore to the arrangement with the spins lying in the basal plane. Recently strong evidence for a spin reorientation of a type similar to the one observed in hematite was found in a Mössbauer spectroscopy (MS) study of the new 2201 type ferrate $\text{BiPbSr}_2\text{FeO}_{6+z}$.²

In the present paper we extended our study to the isostructural ferrate BiPbSrCaFeO_{6+z} prepared as described in Ref. 3, hereafter denoted as sample B and to two other samples obtained after annealing sample B first for 30 h at 700 °C and subsequently 17 h (sample B5) or 24 h at 850 °C (sample B8).

We start with the set of Mössbauer spectra of sample B, taken over a large temperature range, some of them shown in Fig. 1. Between 4.2 and 60 K there is no significant change in the shape of the spectra. Above 60 K the Mössbauer spectra become more complex and an increasing amount of a new phase with different hyperfine parameters appears. At 130 K, i.e., sensibly below the Néel temperature of 245 K the only magnetically split spectrum present belongs to the new phase. A similar behavior was previously observed in the case of $\text{BiPbSr}_2\text{FeO}_{6+z}$.² We have therefore to consider a low-temperature and a high-temperature modification of the same magnetic compound, hereafter denoted as a LT phase and a HT phase.

About 90% of Fe is in the Fe^{3+} state as derived from the values of the hyperfine field (HF) and isomer shift (IS) at 4.2

K. Two more aspects are worth mentioning: (1) the presence of an amount of 10%–12% Fe^{4+} and (2) the occurrence of a paramagnetic phase, appearing at 60 K and increasing steadily to 20% at a temperature of 20 K below the Néel point.

A comparison between the value of the quadrupole splitting (QS) in the paramagnetic regime above T_N and the double of the quadrupole shift q_s in the magnetically ordered range usually allows one to get valuable information about the orientation of the Fe spins in the spin frozen state. In this respect the most important finding is that for the LT phase $2q_s$ is positive and practically equal to the QS value in the paramagnetic range. This result in conjunction with the sym-

FIG. 1. Mössbauer spectra of BiPbSrCaFeO_{6+z} (sample B) taken at several temperatures.

FIG. 2. Concentration c of the HT phase measured in increasing (■) and decreasing (◇) temperature regimes and the angle (An) between Fe spins and c axis vs T for sample B.

metry of the octahedral environment of the Fe ions allowed us to assume a local axial symmetry of the crystalline field at the Fe site and therefore to use for QS and 2qs the equations:

$$QS = (1/4)eQV_{zz} \quad (1)$$

and

$$2qs = (1/2)QS \operatorname{sgn}(V_{zz})(3 \cos^2 \vartheta - 1). \quad (2)$$

Here Q is the ^{57}Fe nuclear quadrupole moment, V_{zz} the axial component of the electrical field gradient (EFG), in our case the projection along the c axis.

For the LT phase we have $2qs = QS = +1.46$ mm/s (mean value), leading therefore to the result $\vartheta = 0$, i.e., the Fe spins are oriented along the c axis as in the low-temperature phase of hematite below the Morin point. Using Eq. (2) one finds for the HT phase to which belong all the magnetically ordered Fe spins above 130 K, the value $\vartheta = 90^\circ$, i.e., a spin orientation in the $a-b$ plane, this time similar to a purely antiferromagnetic hematite above the Morin point.

A first remarkable aspect is the coexistence of both phases over a rather broad temperature interval of about 60 K. A second point is the continuous variation of the relative concentrations of the LT phase with $\vartheta = 0$ and of the HT phase with temperature dependent ϑ .

The first point is not the consequence of a thermal hysteresis as can be seen from Fig. 2 where the concentration of the HT phase measured in both increasing and decreasing temperature regimes lies on the same curve. Concerning the second point it is worth mentioning that subsequent heat treatments gave rise to more complex behaviors as was the case with the samples B5 and B8 for instance. In the former case even at 4.2 K about half of the iron still belonged to the HT phase (Fig. 3). A scrutiny of Figs. 2 and 3 shows that at variance with the way the Morin transition occurs in good

FIG. 3. Concentration c of the HT phase (■) and LT phase (*) of the paramagnetic component (□) and the angle (An) between Fe spins and c axis vs T for the sample B5.

hematite crystals as evidenced in the MS study of Van der Woude⁴ the spin reorientation in BiPbSrCaFeO_{6+z} despite the gradual and anhysteretic character of the transition cannot be designed as a pure second-order phase transition.

In fact, taking the angle ϑ as order parameter for instance, we see that it changes continuously for the HT phase with decreasing temperature, the spins making larger and larger angles with the basal plane. In the same time the amount of the LT phase with the spins only along the c axis increases, involving below 60 K all the Fe atoms in the probably most favorable case of sample B.

Typical dependencies on temperature of the average hyperfine fields of both LT and HT phases, as well as the variation of the concentration of the paramagnetic phase with temperature are shown for the sample B in Fig. 4.

In order to better fit the 4.2 K spectra of sample B, for instance, one needed two sextets with higher HF values of 49.7 and 47.7 T and one with HF = 18.6 T for about 11% of the total iron. The latter HF value can be ascribed to Fe^{4+} ions anyway expected because of a slight overoxidation corresponding to 6.13 oxygen atoms per formula unit. Even at 4.2 K the linewidths of the fitting sextets are rather large and the need for the two sextets with the higher HF values has probably to be correlated to a distribution of Bi and Sr around the apical oxygen ions in the FeO_6 layers, leading to slightly different distortions of the Fe-O distances.

At this point one has to envisage the quasi-two-dimensional character of the layers of FeO_6 octahedrons in the compounds we studied. Two layers of a Bi and Pb oxide with rocksalt structure separate along the c axis two layers of FeO_6 octahedrons. For this reason whereas the distance between two Fe containing planes reaches about 1.3 nm, the distance between two Fe atoms in the basal plane is only 0.4 nm giving rise to a strong structural anisotropy favorable to

FIG. 4. Average hyperfine field H for the HT phase (*) and LT phase (■) and the concentration c of the paramagnetic component (□) vs T for the sample B8.

the single-ion anisotropy of the iron ions and the two-dimensional character of the superexchange interactions. The quasi two dimensionality can explain the relatively low Néel temperature of the compounds studied here (200–250 K) when compared with the Néel temperature of 512 K for $(\text{Bi,Pb})_2\text{Sr}_2\text{BiFe}_2\text{O}_{9+z}$ with double layers of apically connected FeO_6 octahedrons. The lower dimensionality could also be the reason for the HF values at 4.2 K which are 3–5 T lower than the ones found for the FeO_6 multilayer compounds⁵ and makes the spin-reorientation transition more sensitive to local changes of chemical or/and structural nature.

It is worth mentioning that versions of the Morin transition reminiscent of the features we found in our study were also reported in several studies of the influence of crystallinity and impurities on this phase transition. The explanation proposed by de Grave *et al.*⁶ based on the combined influence of porosity, particle size, impurities, and local variations in the strength of the exchange interactions is probably also true for the compounds we studied here. But in order to be more specific we have to try to better define the similar factors which can be dominant in our case. An irregular distribution of the Sr and Ca atoms as important factor can be eliminated because we find the same complex behavior in the case of $\text{BiPbSr}_2\text{FeO}_{6+z}$.² But common to both compounds is the presence of about 10% Fe^{4+} . We believe that the tetravalent Fe ions play the role of the impurities known for their strong influence on the Morin transition of hematite. Because of their smaller radius the Fe^{4+} ions can give rise to local distortions of the Fe–O distances and therefore to local changes in the single ion anisotropy and superexchange. Together with the occurrence of Fe^{4+} ions some regions of the crystals have to accommodate the extra oxygen, most probably in the $(\text{Bi,Pb})\text{O}$ bilayers, giving rise again to local changes in the single-ion anisotropy of Fe^{3+} .

We want to express our thanks to Dr. A. Wieck from the Ruhr University Bochum for allowing us to use the experimental facilities of his Institute and to the Bundesministerium für Forschung und Technologie for financial support.

Magnetization behavior of $(\text{NBu}_4)_2\text{Mn}_2[\text{Cu}(\text{opba})]_3$ and related solvated ferromagnets

S. A. Chavan, R. Ganguly, V. K. Jain, and J. V. Yakhmi^{a)}
Chemistry Division, Bhabha Atomic Research Centre, Bombay 400 085, India

Direct current magnetization studies are reported for the organic ferromagnet $(\text{NBu}_4)_2\text{Mn}_2[\text{Cu}(\text{opba})]_3$ ($T_C=22$ K), where opba stands for *o*-phenylenebis (oxamato), and related compounds obtained by solvating it with dimethylsulphoxide, methanol, and acetonitrile, which have T_C values of 15, 12, and 14.5 K, respectively. $M(H)$ plots for the first two compounds show very little width and criss-cross at low applied field values (<50 Oe). Zero field-cooled magnetization and field-cooled magnetization curves for $(\text{NBu}_4)_2\text{Mn}_2[\text{Cu}(\text{opba})]_3$ nearly overlap and its remanence plot changes sign at 11.5 K, exhibiting a compensation behavior. Negative remanent magnetization has also been observed for the other three compounds. The results are discussed in terms of the ferrimagnetic nature of the building blocks. © 1996 American Institute of Physics. [S0021-8979(96)09108-7]

The occurrence of spontaneous magnetization in molecular organic materials was first reported in 1986.¹ Since then different categories of molecular ferromagnets have been synthesized depending on whether the unpaired electrons reside (i) in *p* orbitals only; (ii) in both *p* and *d* orbitals; and (iii) in *d* orbitals only. Kahn's group has synthesized a number of organic ferromagnets belonging to the last category by using bimetallic quasi-one-dimensional chains comprising antiparallel alignment of alternating uncompensated spins as building blocks.²⁻⁵ A typical example of such a bimetallic chain is $\text{Mn}^{\text{II}}\text{Cu}^{\text{II}}(\text{obbz}) \cdot n\text{H}_2\text{O}$ [obbz=oxamido bis benzoato] with an antiferromagnetic interaction between the adjacent local spins $S_{\text{Mn}}=5/2$ and $S_{\text{Cu}}=1/2$ separated by oxamido and carboxylato bridging groups which transmit the magnetic effects. When these ferrimagnetic chains are assembled appropriately in a three-dimensional lattice, interchain interactions may, under suitable conditions, lead to ferromagnetic order as happens in the case of $\text{MnCu}(\text{obbz}) \cdot \text{H}_2\text{O}$ ($T_C=14$ K).⁵ Attempts have been made to raise the Curie temperature (T_C) by increasing the dimensionality of the bimetallic assemblies so as to strengthen the interchain interactions.⁶ For instance, cross-linking the one-dimensional ferrimagnetic $\text{Mn}^{\text{II}}\text{Cu}^{\text{II}}$ chains in the compound $\text{MnCu}(\text{opba})(\text{DMSO})_3$ [where opba stands for *o*-phenylenebis(oxamato) and DMSO for dimethylsulphoxide] results in a two-dimensional $\text{Mn}_2^{\text{II}}\text{Cu}_3^{\text{II}}$ network, where Mn atoms are surrounded by three Cu (opba) groups, instead of two, and yields ferromagnetism at 15 K in $(\text{NBu}_4)_2\text{Mn}_2[\text{Cu}(\text{opba})]_3 \cdot 6\text{DMSO} \cdot \text{H}_2\text{O}$ and at 22.5 K in its desolvated analog $(\text{NBu}_4)_2\text{Mn}_2[\text{Cu}(\text{opba})]_3$.^{7,8} These compounds are soft magnets with $M(H)$ curves exhibiting very narrow hysteresis loops, with coercive fields of 10 Oe or lower at 4.2 K.⁹ In this article, we report the results of our dc magnetization studies on the series of ferromagnetic compounds $(\text{NBu}_4)_2\text{Mn}_2[\text{Cu}(\text{opba})]_3 \cdot \text{S}$, where S stands for solvent molecule, including the above-mentioned $(\text{NBu}_4)_2\text{Mn}_2[\text{Cu}(\text{opba})]_3 \cdot 6\text{DMSO} \cdot \text{H}_2\text{O}$ and the $(\text{NBu}_4)_2\text{Mn}_2[\text{Cu}(\text{opba})]_3$, hereafter called **A** and **B**,

respectively, and two other related ferromagnetic compounds **C** ($T_C=12$ K) and **D** ($T_C=14.5$ K) obtained by solvating **B** with methanol (CH_3OH) and acetonitrile (CH_3CN), respectively. We report negative thermoremanent magnetization for all these compounds, a novel phenomenon observed for the first time, and a compensation behavior leading to valleylike remanence plots for samples **B** and **C**.

The sample **A** was synthesized following the procedure given by Stumpf *et al.*⁷ A part of the sample **A** was heated at 175 °C for ~3 h under vacuum to remove the solvent molecules $6\text{DMSO} \cdot \text{H}_2\text{O}$ and was called **B**. The samples **C** and **D** were obtained by solvating **B** with methanol and acetonitrile, respectively. ac susceptibility measurements made on samples **A**, **B**, **C**, and **D** using an Air Products Division susceptometer with EG & G Model 5208 lock-in amplifier exhibited a sudden divergence at 16, 22, 12, and 14.5 K, respectively. The dc magnetization measurements were made using EG & G P.A.R. Model 4500 Vibrating Sample Magnetometer fitted with an 8 kOe Walker electromagnet and Tide-water bipolar power supply both as a function of temperature, $M(T)$, and applied field, $M(H)$. A Hall-probe Gaussmeter was used to check the absence of residual field between the poles down to <1 Oe.

Zero field-cooled magnetization (ZFCM) data was recorded by cooling the sample down to 5 K in zero applied field, switching the applied field (10 Oe) on at this temperature and recording the magnetization while warming the sample up. Field-cooled magnetization (FCM) data was collected after cooling the sample in 10 Oe field and recording the data while warming up, keeping the field on. Next, remanent magnetization (REM) data was taken after cooling the sample in 10 Oe field to 5 K, and recording the data while warming up after reducing the field to zero (which is accomplished via the software command to the bipolar power supply). It was ensured that the applied field as measured by the Hall probe was indeed zero before taking remanence measurements.

Figure 1 shows the ZFCM, FCM, and REM data as function of temperature for the sample **A**. The ZFCM and FCM

^{a)} Author to whom correspondence should be addressed. Electronic mail: yakhmi@magnum.barc1.ernet.in

FIG. 1. ZFCM, FCM, and REM data for the sample A. REM data for a standard Ni sample and an organic ferromagnet, $\text{MnCu(obbz)} \cdot 1\text{H}_2\text{O}$ are also shown for comparison.

magnetization plots for the sample A showed conventional behavior with a hump below T_c in the ZFCM as reported by Stumpf *et al.*,⁷ except that the magnitudes of ZFCM and FCM were 80 and 285 memu/g in our case. The published work in literature on different ferromagnetic materials reports positive values for remanence. The remanence for the sample A, however, showed negative values remaining nearly constant (-285 memu/g) between 5 and 13 K, becoming zero at ~ 16 K upon warming. The observation of negative remanence is a novel and intriguing observation. One obvious question that comes to mind is whether it has been caused by any residual negative field present between the pole pieces of the electromagnet. As mentioned earlier, we ensured before making any remanence measurements that the residual field is brought to zero (within ± 1 Oe). The sample A showed negative REM behavior even when it was cooled under a higher applied field of 50 Oe before recording the data. In order to give further credibility to our data, we also present REM data taken on a standard Ni sample and another organic ferromagnet $\text{MnCu(obbz)} \cdot 1\text{H}_2\text{O}$ ($T_c = 14$ K),¹⁰ which show positive values of REM, as expected.

Figure 2 shows the ZFCM, FCM, and REM data for B. The ZFCM curve for ferromagnets, including those belonging to the category of bimetallic organic ferromagnets reported thus far, always lie much lower than the FCM because the domain walls do not move freely. However, the ZFCM plot for the sample B is only marginally lower than the FCM

FIG. 2. ZFCM, FCM, and REM data for the sample B. REM plots for the samples C and D are also shown.

for $5 < T \leq 13$ K. Both ZFCM and FCM overlap for $T > 13$ K and even criss-cross a number of times, which is quite rare and implies that the domain walls are able to move rather freely. The remanence value for B which was about $+50$ memu/g at 5 K, dropped sharply upon warming becoming zero at 11.5 K and attained negative values between 11.5 and 19 K, becoming positive again for temperatures above 20 K, a valleylike feature.

ZFCM and FCM curves for the sample D nearly overlapped (like for B). The REM plot for D (Fig. 2) is similar in shape to that of sample A. REM plot for the methanol-solvated compound C, on the other hand, showed a valleylike feature (Fig. 2) but the values remain negative between 5 and 12 K.

The negative values of remanence as well as the valleylike feature have never been observed or reported for ferromagnetic samples. In fact, in most cases the values of Curie temperature is identified as the temperature where the value of REM falls exactly to zero. It should be noted that the magnitude of REM may vary among different polycrystalline samples of a particular ferromagnet because it is generally recognized that it is influenced by sample dependent factors like the grain size and shape. The valleylike feature in the

FIG. 3. $M(H)$ plots for the samples **A**, **B**, **C**, **D**, and **Ni** recorded at 5 K under applied field of ± 500 Oe.

REM plot indicates a compensation behavior which can possibly arise from the ferrimagnetic nature of samples, the basic building blocks for our samples being the ferrimagnetic $\text{Mn}_2^{\text{II}}\text{Cu}_3^{\text{II}}$ planar units.⁷ A compensation behavior can be explained if one considers the two individual sublattices separately as ferromagnetic, each with its own critical temperature and $M(T)$ curve. When combined antiferromagnetically, the net magnetization could take a variety of shapes, including negative values and a compensation point at a temperature where a complete cancellation occurs.

Figure 3 shows M vs H plots at 5 K for the samples **A**, **B**, **C**, **D**, and **Ni** (standard, for comparison) all recorded under the application of ± 500 Oe field and identical conditions. The plots for **A** and **B** are nearly S-shaped curves with very little width (hysteresis), the low-field (-40 – $+40$ Oe) portion, in particular, exhibiting a criss-crossing between the curves corresponding to increasing or decreasing field. The M vs H plot for the sample **D**, too, showed little width with absence of hysteresis at low applied fields. The $M(H)$ plot for the sample **C**, on the other hand, showed comparatively a substantial width, apparently an influence of the solvent molecules, but no criss-crossing. Samples **A** and **B** undergo saturation at ~ 300 Oe. The sample **C** saturates at ~ 400 Oe whereas the saturation field for **D** appears to be > 500 Oe.

In summary, we observe three different kinds of rema-

nence behavior for the four samples studies, whose T_C values range between 12 and 20 K: (i) sharp transition to negative values of remanence for the samples **A** and **D**; (ii) a valleylike feature for **B**, with a compensation feature resulting in a change of sign at 12 K; and (iii) a valleylike feature for **C** but the remanence keeping negative at all temperatures below T_C , indicating that the compensation point may be lying much below our lowest temperature of measurement, viz., 5 K. These observations indicate that the unusual magnetization behavior is inherent in the $(\text{NBu}_4)_2\text{Mn}_2[\text{Cu}(\text{opba})_3]$ assembly. The compounds **A**, **B**, and **D** exhibited S-shaped $M(H)$ hysteresis plot with hardly any measurable width, indicating soft ferromagnetic behavior whereas the $M(H)$ loop ($H_{\text{app}} = \pm 500$ Oe) for **C** showed a substantial width.

The only other reports of unusual magnetic behavior are the observation of (i) a strong negative magnetization below 30 K for a molecular ferromagnet $(\text{NBu}_4)\text{Fe}^{\text{II}}\text{Fe}^{\text{III}}(\text{C}_2\text{O}_4)_3$ by Peter Day and co-workers¹¹ and (ii) a negative, valleylike, rotational remanent magnetization for lithium chromium ferrite.¹² At this stage, the mechanism giving rise to the observation of negative remanence in our samples is not clear and is at best speculative. In general, a negative remanent magnetization could imply a field-induced magnetization effect in which a sample, which is magnetic in the presence of a field, becomes diamagnetic in the absence of a field. However, these bimetallic organic magnets are known to exhibit spontaneous magnetization below T_C even in the absence of an applied field. It is possible that the anomalous solvent-sensitive thermoremanent magnetization data, including a compensation behavior for the samples **B** and **C** and the criss-crossing of $M(H)$ plot in some cases, arise due to an antiferromagnetic coupling of hard and soft regions.

Magnetic properties and grain growth stability of nanocomposite Fe-ZrO₂ granular solids prepared by mechanical milling

S. C. Axtell and R. Schalek

Department of Mechanical Engineering and Center for Materials Research and Analysis,
University of Nebraska, Lincoln, Nebraska 68588-0656

Correlations between the grain size [or the diffracting particle size (DPS)] and the magnetic properties of mechanically milled Fe-ZrO₂ nanocomposite powders are reported. Nanocomposite powders with iron volume fractions below, near, and above the percolation value were annealed at temperatures between 573 and 1083 K and investigated. The composite as-milled powders exhibited enhanced coercivities (>300 Oe) compared to similar mechanically milled iron powders. The iron diffracting particle size (grain size) as a function of annealing temperature showed two regimes. The first regime, corresponding to temperatures at and below 773 K, consisted of enhanced coercivities and remanence ratios with a relatively stable iron diffracting particle size of ~25 nm. In the second temperature regime, above 773 K, the DPS increased, but remained well below the value for pure iron. Concomitant with this increase, large reductions in the coercivities were observed in the second regime. © 1996 American Institute of Physics. [S0021-8979(96)09208-3]

I. INTRODUCTION

Granular metals consist of nanometer-size metal granules homogeneously distributed in a matrix. The unique microstructure results in a large variety of interesting properties.¹ Granular metal systems have been successfully fabricated by various deposition² and milling techniques³ with metals Fe, Ni, Co, and Au, in various matrices (e.g., SiO₂, Al₂O₃, and MgO). In granular materials, the critical parameters affecting the magnetic properties include the metallic particle size, and the metal volume fraction (x_v) relative to the percolation volume fraction (x_p). For many granular systems $x_p \approx 0.5$.^{4,5} Granular solids with $x_v > 0.5$ consist of metal regions forming a continuous matrix, while for $x_v < 0.5$ the metal forms isolated particles.

In recent years mechanical milling has demonstrated the ability to produce nanocomposite granular powders.^{3,6} This technique has some advantages over thin film deposition techniques since large quantities of material may be produced quickly and cheaply. Furthermore, the grain size (diffracting crystallite size) of the constituent materials can be easily controlled by varying the milling parameters. This study attempts to correlate the magnetic properties of mechanically milled Fe-ZrO₂ nanocomposites with the iron diffracting particle size as a function of annealing temperature. A monodisperse, amorphous ZrO₂ powder that crystallizes with a diffracting particle size of 5.5 nm was chosen as the matrix. Iron volume fractions above, near, and below x_p were investigated.

II. EXPERIMENTAL PROCEDURES

The starting powders consisted of -100 mesh Fe (Cerac) and amorphous ZrO₂ powders. The Fe and the ZrO₂ powders were combined at compositions of Fe_x(ZrO₂)_{1-x} where $x=0.32, 0.52$, and 0.70 , where x is reported in volume percent. Using a ball-to-powder mass ratio of two, the powders were milled in a Spex 8000 Mixer/Mill under an argon atmosphere using three 12 g tungsten carbide (WC) balls in a WC lined grinding chamber. X-ray diffraction (XRD) pat-

terns were acquired using a Philips 3100 x-ray diffractometer outfitted with a copper x-ray tube and graphite monochromator. The XRD patterns were collected using a 0.2° receiving slit and a 1°-4° variable divergent slit. The single-peak profile Fourier analysis technique described by Ganesan *et al.*⁷ was used to calculate the average diffracting particle size (DPS) from the (110) iron x-ray peak. The powders were annealed for 1 h in flowing argon at temperatures from 573 to 1073 K. Milled powders were mixed with paraffin to prevent magnetization reversal via particle rotation when measuring hysteresis loops.

III. RESULTS AND DISCUSSION

Figure 1 shows the average iron DPS as a function of composition and annealing temperature. The as-milled DPS (represented by the 300 K value) ranges from a steady state 6.5 nm [below the single domain size of ~10 nm (Ref. 8)] for pure iron to 19.6 nm for the $x=0.70$ powder. The dependence of the DPS on the composition is a complicated function of co-deformation processes occurring during milling. These results indicate that, though the milling times were held constant, the conditions for obtaining the steady state iron DPS for the composite powders were not realized and, hence, the defect structure of the powders is slightly different.

The DPSs of the $x=0, 0.32$, and 0.52 nanocomposites are relatively stable (<25 nm) for temperatures of 773 K and below. The rapid grain growth observed above 773 K is consistent with other reports of where accelerated grain growth in single and two-phase nanocrystalline materials occurred above a critical temperature.^{9,10} At 873 K and above, larger changes in the DPS are seen, with the pure iron powders showing a tremendous increase relative to $x=0.32$ and 0.52 . Two temperature regimes can be identified from the data in Fig. 1 for $x=0, 0.32$, and 0.52 : (1) for $T \leq 773$ K, the DPS remains near 25 nm and (2) for $T > 773$ K, where significant increases in the DPS are seen. Interestingly, the annealing temperature corresponding to this division coincides not only

FIG. 1. The average diffracting particle size as a function of powder composition and annealing temperature. The large increase in iron DPS at 873 K indicates a demarcation point for grain growth stability. (Note: compositions are reported in volume percent.)

with large increases in the DPS, but also with the crystallization temperature of the ZrO₂ powder.

The behavior of the $x=0.70$ powders provides further evidence of poor thermal stability of the iron regions for DPSs ≥ 20 nm. In this case, the DPS increases substantially from the as-milled value of 19.6 nm upon annealing at low temperatures, but tends to stabilize at higher temperatures. This behavior suggests that short-range iron diffusion and defect removal increases the DPS. At higher temperatures, the DPS of the composited powders (including the $x=0.70$) is suppressed by the ZrO₂ particles when compared to the pure iron powder.

Hysteresis loops of the milled powders were studied as a function of iron volume fraction and annealing temperature to facilitate understanding of the effects of the nanoscaled iron structure with respect to the separation distance of the iron particles. The coercivity, H_c , as a function of annealing temperature is shown in Fig. 2 for each concentration. Error bars (omitted for clarity) are smaller than the symbol size. H_c is enhanced in the as-milled condition ($T=300$ K) for all composites. H_c is a maximum for $x=0.52$ (a value near x_p) with a value of 314 Oe. The $x=0.32$ and 0.70 powders show H_c values intermediate to the pure iron and $x=0.52$ powders. This trend is consistent with that reported by Xiao and Chien¹¹ for Fe-SiO₂ films, but disagrees with the results reported by Ambrose *et al.*⁶ and Linderöth and Pedersen³ for ball-milled Fe-Al₂O₃. The ball-milled Fe-Al₂O₃ powders exhibit peak coercivity enhancements at volume fractions of 0.4 and 0.3, respectively. Comparing the coercivity measurements with the DPS values indicates that, though significantly different H_c were measured for the $x=0.32$ and 0.52 powders, the DPS values are very similar. This result is most likely due to a combination of the milling conditions and composition. For instance, the $x=0.52$ powders possibly

FIG. 2. The dependence of the coercivity on the powder composition and on the annealing temperature. Significant decreases in the coercivity are observed for $T > 773$ K. (Note: compositions are reported in volume percent.)

have a large fraction of single-domain regions, while the $x=0.32$ powders have a large fraction of superparamagnetic regions, although the average DPS in both cases is similar.

Slight decreases in H_c are observed for annealed powders. In particular, gradual decreases in the coercivity are seen for the $x=0.32$ and 0.70 powders, while the $x=0.52$ powder shows a gradual decrease followed by a large decrease (a change of 187 Oe) for $T > 773$ K. This temperature correlates well with the demarcation of the DPS regimes identified by Fig. 1. In addition, the heat treatments cause the DPS to double in size for all the powders except the $x=0.70$ sample. To eliminate iron oxide formation as a possible cause to the decrease in coercivity, x-ray diffraction analysis was performed on the annealed powders. No oxide peaks were observed; however, thin interfacial oxides between particles may be undetectable and possibly contribute to de-

FIG. 3. The dependence of the remanence ratio on the annealing temperature and particle composition. (Note: compositions are reported in volume percent.)

creases in H_c .¹² In the second temperature regime, the powders with x above or near x_p ($x=0.32$ and 0.52) retain an increased coercivity, while the powder with iron concentration below x_p (DPS=72 nm) has a coercivity approximately equal to the pure iron case (DPS=116 nm).

As shown in Fig. 3, a larger remanence ratio is also observed for the composite powders in the first temperature regime. Again, the demarcation temperature corresponds to 773 K and a DPS of ~ 25 nm. These results indicate that the H_c and the remanence ratio are rather weakly dependent on the DPS for values $< \sim 25$ nm, but increase in sensitivity for larger DPSs.

IV. CONCLUSIONS

The diffracting particle size and the magnetic properties of mechanically alloyed Fe-ZrO₂ nanocomposite powders annealed at temperatures between 573 and 1083 K were investigated. Two temperatures regimes were identified. In the first regime, ($T \leq 773$ K) the composites displayed enhanced coercivities and remanence ratios, with the iron DPS remaining relatively stable at ≤ 25 nm (for the $x=0.32$ and 0.52 samples). For $T > 773$ K, the DPSs increase and concomitant reductions in the magnetic properties are observed.

We developed a model to completely explain the domain wall existing at the interface of an amorphous Y-Co/Gd-Co bilayer. Samples produced by sputtering, were characterized by Rutherford backscattering spectrometry and transverse magneto-optical Kerr effect. From the experimental parameters we determined the thickness (δ) and relative position (Δ) of the domain wall, and also the exchange constant (A) for the Co-Co atom pair. The room temperature value of A was found to be $(4.8 \pm 1.4) \times 10^{-8}$ erg/cm. © 1996 American Institute of Physics.

[S0021-8979(96)15208-X]

I. INTRODUCTION

A macroscopic ferri-ferromagnetic transition was reported^{1,2} for the sandwich system composed of amorphous RE-Co layers, where RE=Y and Gd. The Gd and Co atoms are antiferromagnetically coupled, while the Y-Co amorphous alloys only the Co atoms contributes magnetically. Due to the exchange interaction, all the Co magnetic moments are aligned. When an in-plane magnetic field, larger than the magnetic transition field (H_t) is applied parallel to the easy axis direction, a reversion on the Gd-Co magnetic moment occurs. As a consequence, a domain wall (DW) is created at the interface region. This DW is large and parallel to the interface and minimizes the exchange interactions between the cobalt atoms. Our intention here, is completely characterize this DW. We produced amorphous YCo₂/GdCo₂ bilayers on glass substrates. Using transverse magneto-optical Kerr effect (TMOKE) magnetometry we can determine the magnetic properties for each layer in each sample.

II. EXPERIMENT

The samples are composed of magnetic layers of nominal composition YCo₂ and GdCo₂ deposited on a glass substrate. Layers of Si₃N₄ are used under and over the magnetic layers, to protect the samples. The thickness of the magnetic layers ranges from 400 to 1200 Å. To produce the amorphous films, we used dc triode sputtering, with the substrate cooled to liquid N₂ temperature. A magnetic field of 300 Oe was applied during the deposition, to induce an in-plane anisotropy. Film thickness and composition were determined by Rutherford backscattering analysis (RBS). We used a TMOKE to characterize the magnetization of the films. It is based on a laser-diode ($\lambda=670$ nm), giving a 60° incident p -polarized wave. A Helmholtz coil produced a 180 Oe maximum magnetic field H_{dc} and frequency 30 mHz. The TMOKE was used to determine the hysteresis loops and the magneto-optical transversal susceptibility (χ_t).³ In the latter case a second coil, perpendicular to the first one, produced an in-plane oscillating magnetic field H_{ac} of ~ 1 Oe at a frequency of 5 kHz. The lock-in amplifier was synchronized to this frequency. From the magnetic field dependence of χ_t ,

we determined the anisotropy field (H_k) as the magnetic field corresponding to the peak signal. As H_{ac} , in this case, is applied parallel to the hard axis of the sample, there is neither coercive nor transition effects on this measurement. As the penetration depth of the light is less than each layer thickness, the magneto-optical (MO) signal comes independently from each layer of the sample. The red light (1.85 eV) of the laser can induce an optical process only for the magnetic electrons of the Co atoms, meaning the MO hysteresis loops corresponds only to the magnetic contribution of the Co atoms. To complete the magnetic characterization of the samples, we also used a vibrating sample magnetometer (VSM) and a hysteresis loop tracer.

III. THEORETICAL MODEL

Ndjaka⁴ and Dieny⁵ presented for the sandwich system, a theoretical model for the Bloch wall. It was based on the exchange and Zeeman energies. The measurements on our bilayers give us comparable values of H_t and H_k . Thus we needed to add the effective anisotropy term in our model.

In the model, a and b represent, respectively, the YCo₂ and GdCo₂ materials: $M_{a,b}$ are their saturation magnetizations; $e_{a,b}$ the layer thicknesses and $\delta = \delta_a + \delta_b$ is the total thickness of the DW. $\delta_{a,b}$ is the portion of the DW in each layer. $K_{a,b} = M_{a,b} \times H_{ka,b}/2$ is the effective anisotropy constant, supposed to be uniaxial and in-plane. It is also necessary to define the relative position of the DW, $\Delta = \delta_a/\delta$. The values of Δ range from 0 to 1, corresponding, respectively, to the DW passing from inside layer b to a . The direction of the magnetization inside the DW is supposed to change linearly with position. Our theoretical model describing the DW at the interface of the amorphous bilayer considers the exchange (E_{ex}), the effective anisotropy (E_k) and the Zeeman (E_z) energies. From Chikazumi⁶ we can write each of these terms as:

(1) For $|H| < H_t$ (without DW)

$$E_{z,i} = -M_a H e_a + M_b H e_b, \quad (1)$$

$$E_{ex,i} = E_{k,i} = 0.$$

(2) For $|H| \geq H_t$ (with DW)

$$E_{z,f} = -\frac{M_a H}{2} \left[e_a - \delta \Delta + \frac{\delta \sin(\pi \Delta)}{\pi} \right] \pm \frac{M_b H}{2} \times \left[e_b - \delta(1 - \Delta) - \frac{\delta \sin(\pi \Delta)}{\pi} \right], \quad (2)$$

$$E_{k,f} = \frac{M_a H_{ka}}{2} \left[\frac{\delta \Delta}{2} - \frac{\delta}{4\pi} \sin(2\pi \Delta) \right] + \frac{M_b H_{kb}}{2} \left[\frac{\delta(1 - \Delta)}{2} + \frac{\delta}{4\pi} \sin(2\pi \Delta) \right], \quad (3)$$

and

$$E_{ex,f} = A \pi^2 / \delta, \quad (4)$$

where A is the Co-Co atomic pair exchange constant.

Minimizing the total energy, $E_{tot,f} = E_{z,f} + E_{k,f} + E_{ex,f}$, in relation to Δ , we get

$$-\frac{(M_a - M_b)H}{(M_a H_{ka} - M_b H_{kb})} = \frac{\sin^2(\pi \Delta)}{1 - \cos(\pi \Delta)}, \quad (5)$$

The right-hand side of Eq. (5) is in the range from 0 ($\Delta=1$) to 2 ($\Delta=0$), while the left-hand side is not limited. If its value is negative or larger than 2, this means the DW would be far from the interface. Under these conditions, the energy minimum would not be attained, due to the portion of the layer between the DW and the interface that would have its magnetization inverted relative to the magnetic field. Now, minimizing $E_{tot,f}$ in relation to δ , we can determine the total thickness of the DW,

$$\delta = \pi(2A)^{1/2} \left[M_a H \left(\Delta - \frac{\sin(\pi \Delta)}{\pi} \right) + K_a \left(\Delta - \frac{\sin(2\pi \Delta)}{2\pi} \right) + M_b H \left(1 - \Delta + \frac{\sin(\pi \Delta)}{\pi} \right) + K_b \left(1 - \Delta + \frac{\sin(2\pi \Delta)}{2\pi} \right) \right]^{-1/2}. \quad (6)$$

And, finally, from the equilibrium between $E_{tot,i}$ and $E_{tot,f}$, at $H = H_t$, we have

$$A \pi^2 / \delta_t - H_t (M_b e_b) / 2 = 0, \quad (7)$$

where δ_t corresponds to the DW thickness at $H = H_t$.

Equations (5)–(7) are interdependent and their solution is different for each sample, depending upon its specific magnetic properties. Then, from the values of the $M_{a,b}$, $H_{ka,b}$, $e_{a,b}$, and H_t of the sample, we can determine the magnetic field dependence on δ and Δ , and also the value of A for the Co-Co atomic pair.

TABLE I. Experimental parameters from RBS and VSM measurements.

Composition	Thickness (Å)	m_s (emu)	Area (cm ²)	M_s (emu/cm ³)

FIG. 1. TMOKE hysteresis loop from the Gd-Co side of the bilayer. The vertical axis is the relative variation of the reflectivity.

IV. EXPERIMENTAL RESULTS AND DISCUSSION

The samples were produced with thicknesses of each layer in the range from 400 to 1200 Å. Depending on the sample, the H_t and H_k values were 40–350 Oe and 30–150 Oe, respectively. Here we will present results of one bilayer that represents quite well the utilization of the model. Single-layer films were prepared to determine the saturation magnetization of the Y-Co and Gd-Co layers. In Table I we have the results of the characterization of these three samples, using RBS and VSM.

In Figs. 1 and 2, we have the TMOKE hysteresis loops, respectively, for the Gd-Co and Y-Co sides of the bilayer. These easy axis loops represent only the contribution of the Co atoms, as explained before. It is possible to see for low magnetic fields (<30 Oe), that the Co atoms of both layers are ferromagnetically aligned. At $H \sim 50$ Oe there is the ferri-ferromagnetic transition, with the inversion of the magnetization of the Gd-Co layer. For large values of H , this con-

FIG. 2. TMOKE hysteresis loop from the Y-Co side of the bilayer.

FIG. 3. B vs H curve of the Y-Co/Gd-Co bilayer. At $H \sim 50$ Oe there is a ferri-ferromagnetic transition.

figuration remains stable. The small perturbation visible on the Y-Co side for a magnetic field of about $H = 50$ Oe will be explained later. In Fig. 3 we have the B vs H curve obtained using the hysteresis loop tracer, where B is in mV due to the difficulty of defining the cross-sectional area of the sample. Anyway, the vertical axis can be calibrated using the value of $m_s = 0.023$ emu from Table I. At $H \sim 20$ Oe the coercive field is visible, in agreement with Figs. 1 and 2. From Fig. 3 we can determine the transition field as $H_t = 49$ Oe. Just below the transition we have the magnetic moment of the Co atoms in both layers aligned with the magnetic field, while the Gd moment is in the inverse sense. We will define the magnetic moment of this point as m_s^- , and its value is $\sim 10\%$ of m_s , for this sample. Next, we present in Fig. 4, the TMOKE susceptibility (χ_t) vs H of the Y-Co side of the bilayer. The shape of this curve is typical; it is obtained applying H_{dc} parallel to the hard axis and gives us, from the peak, $H_{ka} = 33$ Oe. In the insert we have the hys-

FIG. 4. TMOKE transverse susceptibility χ_t vs H for the Y-Co side of the bilayer. From the peak, we determine $H_{ka} = 33$ Oe. Insert: hard axis TMOKE hysteresis loops.

teresis loops to the same condition, showing no transition on the hard axis. The measurement on the other side of the same sample (Gd-Co) gives $H_{kb} = 126$ Oe.

Now, applying these experimental results to the theoretical model, we got from Eq. (5), $\Delta = 0.83$ when $H = 49$ Oe. This means 83% of the DW is in the Y-Co layer. Increasing H leads to a reduction in Δ , indicating a displacement of the DW in the direction of the Gd-Co layer. In order to determine simultaneously the value of δ_t and A , we used Eqs. (6) and (7) together with $H_t = 49$ Oe and $\Delta = 0.83$. Then, we obtained $\delta_t = (730 \pm 140)$ Å and $A = (4.8 \pm 1.4) \times 10^{-8}$ erg/cm.

At the transition, 83% of the DW (607 Å) is in the Y-Co layer. This means the DW is at ~ 500 Å from the surface and, since the light penetration depth is of the order of hundreds of Å, we can explain the small signal around H_t in Fig. 2. Before the transition, the magnetization of the Gd-Co layer is in the opposite sense to that of the Y-Co layer. Then we can calculate m_s^- as, $m_s^- = [M_a e_a - M_b e_b] S$, where S is the surface area of the sample, as presented in Table I. This gives us $m_s^- = (2 \pm 2) \times 10^{-3}$ emu. After the transition, both the magnetizations are in the same sense, so that $m_s^+ = [M_a e_a + M_b e_b] S$. We found $m_s^+ = (19 \pm 3) \times 10^{-3}$ emu. This value agrees quite well with the saturation magnetic moment measured in the VSM. It is also ten times larger than the m_s^- value, in agreement with Fig. 3.

V. CONCLUSIONS

We developed a model to completely explain the DW existing at the interface of an amorphous bilayer of Y-Co/Gd-Co. Using parameters measured in our samples, we can calculate the magnetic field dependence of δ and Δ . Both are qualitatively reasonable and consistent with the magneto-optical hysteresis loops. For $H = H_t$, the DW was almost completely in the Y-Co layer. For the $Y_{0.32}Co_{0.68}/Gd_{0.31}Co_{0.69}$ amorphous bilayer analyzed here, $\delta = 730$ Å. The room temperature value of A for the Co-Co atomic pairs was found to be $(4.8 \pm 1.4) \times 10^{-8}$ erg/cm, one order lower than that determined using estimated parameters, in Ref. 5. Our result better agrees to that presented by Raasch,⁷ $A = 2 \times 10^{-7}$ erg/cm, for a $Gd_{21.2}Co_{78.8}$ amorphous film. The Co concentration may be responsible by the difference in these values.

RE_2CuO_4 (RE=rare earth) compounds constitute an interesting family of materials because of their magnetic complexity as well as for their relationship with high T_c superconductors. For R=Gd and heavier rare earths, a weak ferromagnetic component (WF) is observed below ~ 280 K. This component has its origin in a canting of the Cu antiferromagnetic (AF) structure due to a distortion of the oxygen ions between the copper atoms. In this contribution we center our work in Gd_2CuO_4 , which is the only WF compound in the series that can be synthesized at normal pressures. WF can be easily detected by microwave absorption, due to the presence of an associated low field absorption signal.¹ We have synthesized the material by sol-gel methods, allowing a control of grain size, dependent on time, and the final calcination temperature. The microwave absorption results show that the onset point for the WF component shifts from 290 K for the bulk material, to 210 K for particles with an average size of 120 nm. For particles less than 90 nm the WF resonance line is not observed, suggesting the absence of weak ferromagnetism. As the WF component is associated to the AF ordering, we interpret our results as the elimination of the long range order motivated by the particle size reduction. © 1996 American Institute of Physics. Inverse giant magnetoresistance (invited)

J.-P. Renard, P. Bruno, R. Mégy, B. Bartenlian, P. Beauvillain, C. Chappert, C. Dupas, E. Kolb, M. Mulloy, J. Prieur, P. Veillet, and E. Vélú

Inverse giant magnetoresistance (GMR) is obtained in multilayers alternating two ferromagnetic layers F_1 and F_2 with different asymmetry of spin scattering, $\alpha_1 > 1$ and $\alpha_2 < 1$. This is clearly demonstrated in the simple spin-valve system with perpendicular magnetization $\text{Fe}_{1-x}\text{V}_x/\text{Au}/\text{Co}$. With respect to Fe, the FeV alloys with $x=0.18$ and 0.29 exhibit an inversion of the spin scattering coefficients ($\alpha_{\text{Fe}} > 1$, $\alpha_{\text{FeV}} < 1$) due to the change of the densities of states at the Fermi level. The inverse MR of FeV/Au/Co is studied as a function of FeV layer thickness and temperature and compared to calculations based on the Camley–Barnas model. The data show that the inverse GMR is due to the bulk scattering within the FeV layer, which coexists with a substantial interface scattering favoring normal GMR. © 1996 American Institute of Physics.

1. INTRODUCTION

Giant magnetoresistance (GMR)¹⁻³ has been widely studied in a large number of magnetic multilayers. It is now well established that GMR is due to spin-dependent scattering of the conduction electrons in the bulk or at the interface of the ferromagnetic (F) layers.^{4,5} More precisely, the scattering probability, D , for a conduction electron crossing a ferromagnetic layer depends on its spin orientation with respect to that of the majority band so that $D \uparrow \neq D \downarrow$, where $D \uparrow (D \downarrow)$ refers to electrons with spin parallel (antiparallel) to majority spin band. The spin asymmetry of scattering is usually defined by $\alpha = D \downarrow / D \uparrow$.⁶ In a simple system with two ferromagnetic layers F_1 and F_2 , the magnetoresistance ratio, $\Delta R/R$, is given in first approximation by

$$\Delta R/R = (R_{AP} - R_P) / R_P \propto (D_1^\downarrow - D_1^\uparrow)(D_2^\downarrow - D_2^\uparrow), \quad (1)$$

where R_{AP} and R_P are, respectively, the resistances for an antiparallel and parallel arrangement of the magnetization directions of F_1 and F_2 . For equivalent ferromagnetic layers, the resistance is larger for an antiparallel arrangement than for a parallel one ($\Delta R/R > 0$), which is the normal GMR, independently of whether $\alpha > 1$ or $\alpha < 1$. On the other hand, if F_1 and F_2 are different and such that $\alpha_1 > 1$ ($D_1^\downarrow > D_1^\uparrow$) and $\alpha_2 < 1$ ($D_2^\downarrow < D_2^\uparrow$), one would expect an *inverse* GMR ($\Delta R/R < 0$). These mechanisms are sketched in Fig. 1. A more detailed theoretical analysis has been given recently by Hasegawa.⁷

The inverse GMR has been checked by George *et al.*⁸ on a Cu based multilayer in which F_1 is a Fe film and F_2 a 0.4-nm-thick Cr film intercalated between two 1.6-nm-thick Fe films. This structure exhibits the expected inverse MR at low field but also a normal MR, i.e., $dR/dH < 0$ at high field. This relatively complex behavior attributed to the misalignment of the magnetizations of the two Fe layers separated by Cr “makes the inverse MR effect less clear than might have been expected”.⁸

A clearer demonstration of inverse GMR is brought by the simple spin-valve system $\text{Fe}_{1-x}\text{V}_x/\text{Au}/\text{Co}$.⁹ This system was chosen for the following reasons. The scattering rates, $D^{\uparrow, \downarrow}$, are expected to be proportional to the densities of states at the Fermi energy $n^{\uparrow, \downarrow}(E_F)$. For Co, which is a strong ferromagnet, one has $n^\uparrow(E_F) < n^\downarrow(E_F)$, i.e., $\alpha(\text{Co}) > 1$. On the other hand, due to its bcc structure, Fe exhibits a pronounced valley in the density of states with $n^\uparrow(E_F) > n^\downarrow(E_F)$ because the Fermi level lies in the bottom of this valley for the minority spins. The position of the Fermi level for the

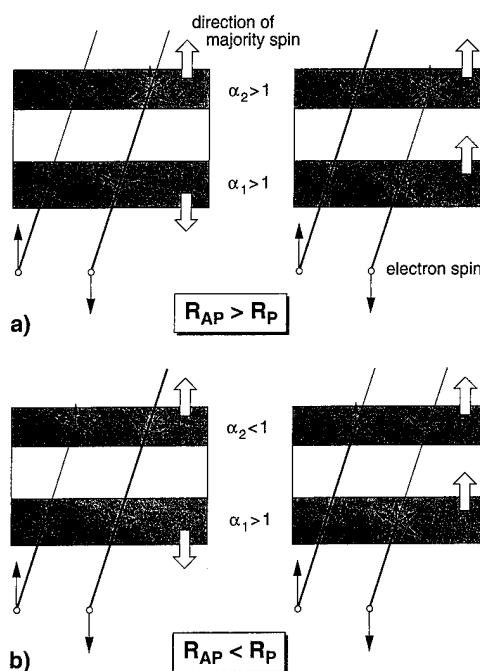

FIG. 1. Schematic picture of the normal (a) and inverse (b) giant magnetoresistance mechanism for a simple structure with two ferromagnetic layers.

FIG. 2. Density of states of Fe (solid line); upper panel: majority spin; lower panel: minority spin. The zero of energy is taken at the Fermi level. Broken line: sketch of the majority spin density of states for a $\text{Fe}_{1-x}\text{V}_x$ alloy, with $x \approx 30\%$.

majority spins, near the upper edge of the 3d band is however such that the spin asymmetry is rather weak, as seen in Fig. 2. The asymmetry can be considerably enhanced by alloying the Fe with a 3d metal of lower valence such as V, as sketched in Fig. 2. Fe and V form solid solutions with a bcc structure over the whole concentration range $0 < x < 1$.¹⁰ The $\text{Fe}_{1-x}\text{V}_x$ alloy is ferromagnetic up to $x = 0.5$ ¹¹ and follows nicely the Slater–Pauling curve.¹² The latter means that upon alloying with V, the majority spin 3d band moves towards higher energy whereas the minority spin 3d band remains essentially unchanged, as sketched in Fig. 2. The maximum asymmetry, and hence maximum inverse MR, is expected for a valence reduction of about one electron, i.e., for a V concentration around 30 at. %. In fact, this band model is rather crude and should be considered as a guide for intuition. First-principles calculations of the electronic structure of $\text{Fe}_{1-x}\text{V}_x$ using a coherent potential approximation (CPA) show little change, with respect to Fe, in the minority band and in the position of the Fermi level in its valley, whereas the majority band is strongly broadened and disordered.¹³

II. SAMPLES AND EXPERIMENTAL TECHNIQUES

The samples are composed of two ferromagnetic layers separated by a Au spacer layer with either a variable Au thickness, t_{Au} , or a fixed Au thickness of 2.35 nm. They are grown at room temperature by evaporation in ultrahigh vacuum with a base pressure of about 10^{-10} mbar on a 28-nm-thick Au buffer layer deposited on a float glass substrate. The protection against oxidation is ensured by a Au cap layer 5 nm thick. The Au buffer layer is deposited at $T \approx 210$ K, at a rate of about 0.06 nm/s. After a 1 h annealing at 450 K controlled by reflection high energy electron diffraction (RHEED), the surface becomes atomically flat, oriented as a (111) plane and made of compact (111) terraces with a few 10 nm lateral size separated by monoatomic steps.¹⁴ The 3-monolayer-thick (3 ML = 0.6 nm) Co film was deposited directly on the Au buffer layer. The FeV alloy was prepared

FIG. 3. Schematic view of the structure of samples 4 and 5, with variable FeV thickness.

by evaporating simultaneously Fe from an alumina crucible and V using an electron gun. Precise determination of the alloy concentration was obtained by measuring separately the Fe and V deposition rates with a quartz microbalance, immediately before and after deposition of the alloy layer. Both measurements gave the same value to within a few percent, which gives confidence that the alloy concentration is constant within the layer. The Co and FeV layers were deposited at a rate of about 1 ML (0.2 nm)/mn. The growth of Co, Fe, and FeV on Au (111) does not follow a layer by layer mode but rather the surface spreads on 2–3 ML for low thickness films. The orientation of hcp Co on Au (111) is (0001)^{14,15} and that of Fe and FeV is (110).¹⁶ Due to the large misfit between Au and the 3d transition metals in these orientations, the lateral coherence of the ferromagnetic films is not very large.¹⁴

Five different samples, (1) $\text{Fe}(0.5)/\text{Au}(t)/\text{Co}(0.6)$, (2) $\text{Fe}_{0.82}\text{V}_{0.18}(0.8)/\text{Au}(t)/\text{Co}(0.6)$, (3) $\text{Fe}_{0.82}\text{V}_{0.18}(0.8)/\text{Au}(t)/\text{Fe}_{0.82}\text{V}_{0.18}(0.8)$, (4) $\text{Fe}_{0.82}\text{V}_{0.18}(t)/\text{Au}(2.35)/\text{Co}(0.6)$, and (5) $\text{Fe}_{0.71}\text{V}_{0.29}(t)/\text{Au}(2.35)/\text{Co}(0.6)$, in which the layer thicknesses are given in nm, have been made following the preparation technique described above. The Au spacer layer of the first three samples and the FeV layer of the last two have a stepped wedge shape with ten different thicknesses ranging from 2 to 11 ML.¹⁷ A schematic view of a sample with variable t_{FeV} is shown in Fig. 3.

The hysteresis loops of the samples were recorded at room temperature by a perpendicular magneto-optical Kerr effect (PMOKE). As discussed later, they exhibit perpendicular magnetic anisotropy and square hysteresis loops except for the largest $\text{Fe}_{0.82}\text{V}_{0.18}$ thickness values. For performing resistivity and magnetoresistance measurements, well separated 1-mm-wide strips were obtained on each step by scribing the metal film with a diamond stylus along the step direction. Electrical contacts were made by sticking gold leads with silver paint on the Au cap layer. Four points measurements were performed with an ac bridge operating at low frequency in the temperature range 1.4–300 K. Perpendicular magnetic fields up to 100 kOe could be applied.

III. EXPERIMENTAL DATA

The hcp Co(0001) and bcc Fe(110) ultrathin films sandwiched in Au(111) have a strong perpendicular interface

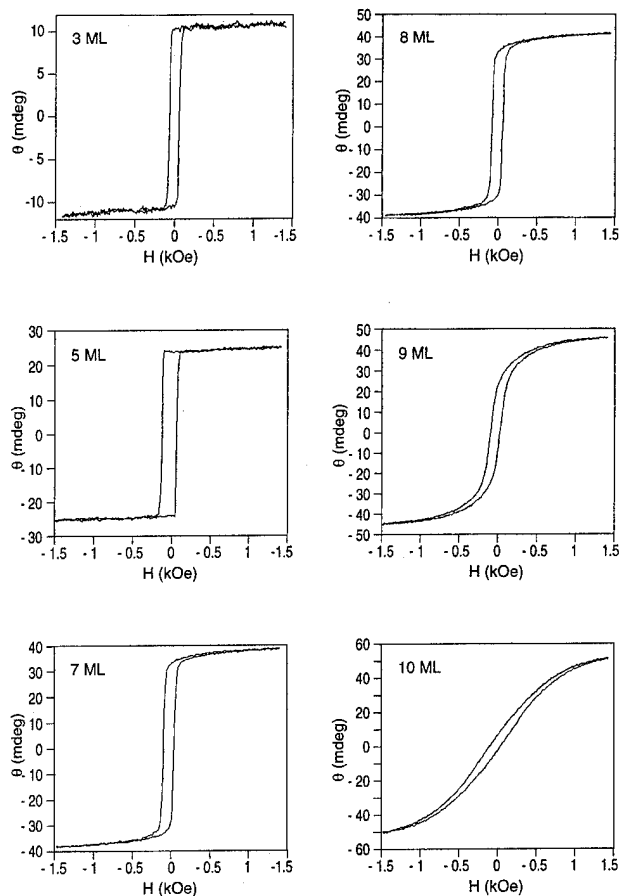

FIG. 4. PMOKE hysteresis loops at room temperature of $\text{Au}/\text{Fe}_{0.82}\text{V}_{0.18}/\text{Au}(111)$ for six different FeV layer thicknesses, 3, 5, 7, 8, 9, and 10 monolayers. Notice the change from perpendicular to parallel magnetization around $t_{\text{FeV}} = 8\text{--}9$ ML.

magnetic anisotropy.^{18,19} The crossover thickness, t^* , below which the magnetization is perpendicular to the film plane is $t^* \approx 9$ ML (≈ 1.8 nm) for Co and $t^* \approx 3$ ML for Fe at room temperature. The PMOKE measurements performed on the FeV alloy ultrathin films also reveal a strong perpendicular anisotropy. This is exemplified by the PMOKE data on $\text{Fe}_{0.82}\text{V}_{0.18}$ in Fig. 4. Square hysteresis loops are obtained at thicknesses below 8 ML and t^* likely lies between 8 and 9 ML. For $\text{Fe}_{0.71}\text{V}_{0.29}$, perpendicular magnetization is observed in the whole investigated thickness range which means that $t^* > 11$ ML. Assuming that the interface magnetic anisotropy remains unchanged when alloying Fe with V and neglecting volume anisotropy, t^* should be inversely proportional to the square magnetization of the FeV alloy. In this frame, with respect to the pure Fe film, t^* should increase by a factor 1.8 for $x = 18\%$ and by 3 for $x = 29\%$, leading, respectively, to $t^* \approx 5.5$ and 9.2 ML. These values are clearly much smaller than the experimental ones which means that the perpendicular magnetic anisotropy is reinforced by alloying Fe with V. Among different possible mechanisms, a bond anisotropy induced by antiparallel alignment of the magnetic moments of Fe and V could be at the origin of this effect.²⁰

For the present experiments, a crucial point is that both ferromagnetic layers have their easy magnetization axis perpendicular to the film plane. In addition, the coercive field of

FIG. 5. PMOKE hysteresis loops of $\text{Fe}/\text{Au}/\text{Co}$ and $\text{Fe}_{1-x}\text{V}_x/\text{Au}/\text{Co}$ trilayers at room temperature for films with a Au interlayer thickness $t = 2.35$ nm (10 ML) and Co thickness $t = 0.6$ nm (3 ML): (a) Fe(0.5 nm); (b) $\text{Fe}_{0.82}\text{V}_{0.18}$ (0.8 nm); (c) $\text{Fe}_{0.71}\text{V}_{0.29}$ (0.8 nm); (d) $\text{Fe}_{0.71}\text{V}_{0.29}$ (2 nm). The higher coercive field is the one of the Co layer. Notice the squareness of the FeV layer magnetization in (b) and (d). In (c), the FeV layer is still paramagnetic ($T_c < 300$ K).

the Co layer, H_1 , is much larger than the coercive field of the Fe or FeV layer, H_2 , and thus a perfect antiparallel alignment of the magnetization directions of the two F films can be achieved over a wide field range, $H_1 > H > H_2$. Moreover, this allows an easy determination of the interlayer coupling from the shift of the minor hysteresis loop as previously reported.¹⁷ Hysteresis curves for $\text{Fe}/\text{Au}/\text{Co}$ (sample 1), $\text{Fe}_{0.82}\text{V}_{0.18}/\text{Au}/\text{Co}$ (s. 2), and $\text{Fe}_{0.71}\text{V}_{0.29}/\text{Au}/\text{Co}$ (s. 5), trilayers with a Au interlayer thickness of 10 AL, measured by polar Kerr rotation at room temperature, are shown in Fig. 5. One notices the fairly rectangular shape of the magnetization curve of the FeV layer, Figs. 5(b) and 5(d), compared to that of the pure Fe layer, Fig. 5(a). The 4-ML-thick $\text{Fe}_{0.71}\text{V}_{0.29}$ layer in Fig. 5(c) is paramagnetic at 300 K.

The MR curves of the same trilayers under perpendicular magnetic field are shown in Fig. 6. The MR curves have the plateau shape usual for two F films with rectangular magnetization loops and different coercivities.^{21,22} While the GMR of $\text{Fe}/\text{Au}/\text{Co}$, Fig. 6(a), is normal (i.e., the largest resistance

FIG. 6. Magnetoresistance curves of $\text{Fe}/\text{Au}/\text{Co}$ and $\text{Fe}_{1-x}\text{V}_x/\text{Au}/\text{Co}$ trilayers with $t_{\text{Au}} = 10$ ML and $t_{\text{Co}} = 3$ ML measured at $T = 60$ K. (a) Fe(0.5 nm); (b) $\text{Fe}_{0.82}\text{V}_{0.18}$ (0.8 nm); (c) $\text{Fe}_{0.71}\text{V}_{0.29}$ (0.8 nm); (d) $\text{Fe}_{0.71}\text{V}_{0.29}$ (2 nm).

corresponds to the antiparallel arrangement of the magnetization directions), the GMR of $\text{Fe}_{1-x}\text{V}_x/\text{Au}/\text{Co}$ is inverse, Figs. 6(b), 6(c), and 6(d). This effect cannot be due to anisotropic magnetoresistance, since the magnetizations of the F layers remain perpendicular to the film plane, only the mutual direction of the magnetizations changes. This is the ideal situation for isolating the spin-valve effect. Although very clear, the observed inverse GMR is small. At low temperature, in similar $\text{Au}/\text{M}/\text{Au}/\text{Co}/\text{Au}$ structures, the maximum value of the GMR, $\Delta R/R$, is about 8% for $\text{M}=\text{Co}$, 3% for $\text{M}=\text{Fe}$ and -0.8% in the best case for $\text{M}=\text{Fe}_{1-x}\text{V}_x$. One may point out that the strong reduction of GMR from Co to Fe reflects a decrease in $(D\downarrow - D\uparrow)$ that we attribute crudely to the fact that $n^\uparrow(E_F)$ and $n^\downarrow(E_F)$ become closer together. Such a MR reduction has also been observed from Co/Cu to Fe/Cu multilayers.²³

It should be pointed out that, if inverse MR has been observed at low temperature in all the investigated FeV/Au/Co samples, rather different values were obtained in two samples with identical structure and composition ($x=0.18$), prepared in two different deposition runs. For the sample 2 with $t_{\text{Au}}=2.35$ nm, the MR was found to be slightly positive at 300 K and amounts to -0.2% at 60 K. For sample 4 with $t_{\text{FeV}}=4$ ML, the MR amounts to -0.13% and -0.69% , respectively, at 300 and 60 K. These two samples only differ by the quality of the Au buffer on which they were grown. For sample 2, the RHEED pattern revealed a larger roughness of the buffer than for sample 4. Since the interface roughness strongly influences the scattering of the conduction electrons and thus, the MR,^{24,25} one can anticipate that interface scattering cannot be neglected in the FeV/Au/Co samples.

A confirmation that the inverse GMR is due to a difference in sign of $(D\downarrow - D\uparrow)$ for FeV with respect to Co is given by the MR of sample 3, FeV/Au(t)/FeV. Its MR is barely measurable, except for Au thicknesses corresponding to the first peak, $t=5$ ML, and to the second peak, $t=10$ and 11 ML of antiferromagnetic coupling.²⁶ A normal (i.e., always positive) MR is observed in agreement with Eq. (1), $\Delta R/R = +0.024$ and $+0.16\%$ for $t=5$ and 10 AL, respectively, at 1.4 K.

The rectangular shape of the curves of resistivity versus magnetic field allows a reliable measurement of $\Delta R/R$. The MR dependence with the FeV layer thickness has been studied on samples 4 and 5. The temperature dependence has been investigated on all samples; preliminary measurements on samples 2 and 5 have been reported previously.⁹ In addition, the exchange coupling between the Co and FeV layers has been measured by the technique of minor hysteresis loops, previously initiated in MOKE studies of Co/Au/Co.¹⁷ An oscillatory behavior versus the Au spacer thickness, quite similar to that reported in Fe/Au/Co,²⁷ is observed.

The experimental data for $\Delta R/R$ vs t_{FeV} are shown in Fig. 7, for two temperatures, $T=60$ K and $T=300$ K. The magnitude of inverse MR in the two studied samples, with $x=0.18$ and $x=0.29$, increases with t_{FeV} . This clearly establishes that the inverse MR is mainly due to a bulk scattering process. Indeed, for predominant interface scattering, the magnitude of MR should decrease with increasing t_{FeV} .

FIG. 7. Magnetoresistance vs FeV thickness, t_{FeV} , in two $\text{Fe}_{1-x}\text{V}_x/\text{Au}/\text{Co}$ samples, 4 and 5, with variable t_{FeV} at $T=60$ K and $T=300$ K. The full squares and circles are the experimental data for sample 4 ($x=0.18$), respectively, for $T=60$ and 300 K. The open squares and circles correspond to sample 5 ($x=0.29$). The full lines are the results of calculations based on the Camley-Barnas model, with the parameters given in Table I (see Sec. IV).

However, the relatively fast MR variation at low FeV thicknesses suggests that interface scattering is superimposed to bulk scattering. This point will be discussed in detail in Sec. IV.

The temperature dependence of MR for sample 4 at different FeV thicknesses is shown in Fig. 8. A relatively strong temperature dependence is observed for all FeV thickness, especially for the lowest ones, 2 and 2.5 ML, for which the MR tends to become positive near 300 K.

IV. DISCUSSION

In order to interpret the experimental MR data in FeV/Au/Co, MR calculations based on the Camley-Barnas model,³ have been developed. In contrast to previous calculations on (Au/Co) multilayers with very small Co thicknesses,²⁸ we have taken into account in addition to the interface scattering, the bulk scattering processes in the FeV

FIG. 8. Magnetoresistance vs temperature for sample 4 ($x=0.18$) at different FeV layer thicknesses. From the top to the bottom, $t_{\text{FeV}}=2$ ML (open squares), 2.5 ML (grey circles), 3 ML (black circles), 4 ML (grey squares), and 8 ML (black squares). The full lines are guides for the eye.

TABLE I. Spin-dependent mean free paths λ_{\uparrow} , λ_{\downarrow} and spin-dependent interface scattering coefficients D_{\uparrow} and D_{\downarrow} for $\text{Fe}_{1-x}\text{V}_x$ ($x=0.18$ and $x=0.29$) at $T=60$ and 300 K.

		λ_{\uparrow} (nm)	λ_{\downarrow} (nm)	D_{\uparrow}	D_{\downarrow}
$\text{Fe}_{0.82}\text{V}_{0.18}$	60 K	2.2	4.3	0.27	0.33
	300 K	1.8	2.7	0.27	0.33
$\text{Fe}_{0.71}\text{V}_{0.29}$	60 K	1.5	5.0	0.45	0.55
	300 K	1.2	2.2	0.45	0.55

layer by means of two different mean free paths, λ_{\uparrow} and λ_{\downarrow} , for conduction electrons, respectively, with spin parallel and antiparallel to the FeV majority spin. The spin-dependent scattering at FeV/Au interfaces is taken into account by means of two scattering coefficients D_{\uparrow} and D_{\downarrow} . The other parameters in the calculation are the coefficients of specular reflection at the Au surfaces, R_1 at the bottom of the Au buffer, and R_2 at the top of the Au cap layer, the spin-dependent transmission coefficients T_{\uparrow} and T_{\downarrow} across the Co film supposed of negligible thickness and the electron mean free path in Au, λ . These latter parameters are well known from previous resistivity measurements on single Au films²⁹ and from our MR studies of (Au/Co) multilayers.³⁰ The following fixed values were used: $R_1=0.85$, $R_2=0.5$, $T_{\uparrow}=0.7$, $T_{\downarrow}=0.1$, $\lambda(60\text{ K})=120\text{ nm}$ and $\lambda(300\text{ K})=32\text{ nm}$. In addition, in order to reduce the number of fit parameters of FeV layers, the mean interface scattering at FeV/Au interface has been fixed to a value close to that of Co/Au interface, i.e., $(D_{\uparrow}+D_{\downarrow})/2 \approx 0.3-0.5$. Finally, three parameters characteristic of the FeV layer, λ_{\uparrow} , λ_{\downarrow} , and $(D_{\downarrow}-D_{\uparrow})$, were varied for minimizing the fit variance.

For both samples investigated, reliable values of these parameters, given in Table I, have been obtained at 60 and 300 K. A comparison between the experimental data and the calculated MR vs t_{FeV} curves is shown in Fig. 7. The fit between experiment and calculation is fairly good for $x=0.18$ (sample 4) but not so satisfactory for $x=0.29$, due to some dispersion in the experimental data and to the fact that T_c is low at the smallest FeV thicknesses. An interesting feature is that both interface and bulk spin-dependent scattering by FeV films are needed to fit the experimental data and that these scattering processes are competing; the interface scattering favors normal GMR, $D_{\downarrow} > D_{\uparrow}$ ($D_{\downarrow}/D_{\uparrow} \approx 1.2$), whereas the bulk scattering leads to inverse GMR, $\lambda_{\uparrow} < \lambda_{\downarrow}$. The fit values for λ_{\uparrow} , λ_{\downarrow} , D_{\uparrow} , and D_{\downarrow} are reported in Table I. The α values ($\alpha = \lambda_{\uparrow}/\lambda_{\downarrow}$) obtained for bulk FeV at 60 K, $\alpha(x=0.18)=0.5$ and $\alpha(x=0.29)=0.3$ are in qualitative agreement with α for dilute V impurities in Fe ($\alpha \approx 0.13$).³¹ Furthermore, the average mean free path for $x=0.18$ is consistent with the resistivity data on FeV alloys.³² The observed decrease of λ_{\uparrow} and λ_{\downarrow} at 300 K can be attributed to the phonons. On the other hand, $(D_{\downarrow}-D_{\uparrow})$ does not change between 60 and 300 K. One could expect to increase the magnitude of inverse MR with increasing x . Nevertheless, samples 4 and 5 have about the same MR. In fact, sample 5 ($x=0.29$) exhibits a larger interface scattering than that of sample 4 ($x=0.18$), which reduces the magnitude of its inverse MR.

FIG. 9. Magnetoresistance of Co (2 nm)/Au (1.65 nm)/Co (0.6 nm) in field parallel to the film plane. An apparent inverse GMR is observed at low field, due to an initial increase with field of the angle between the magnetizations of the Co layers.

The qualitative difference between bulk and interface scattering could be explained in the frame of the simple band model of Sec. I. At the interface between Au and Ag and 3d metals, it is well known that the 3d band is strongly narrowed, leading to enhanced interface magnetic moments.³³ This narrowing gives rise to a better filling of the majority band and thus, to a decrease of the density of states for majority spin with respect to the bulk. The normal spin-dependent interface scattering is likely the major difficulty to produce inverse GMR.

Finally, we would like to emphasize that nonintrinsic inverse GMR can occur in multilayers where the magnetizations of successive layers are not colinear. This is exemplified Fig. 9 showing the GMR of Au/Co(2)/Au(1.6)/Co(0.6)/Au in field parallel to the film plane. In a high magnetic field, the magnetizations of the Co films are aligned parallel to the field leading to a low resistance state. Then, in decreasing field the magnetization of the thinner Co film, 0.6 nm thick, becomes progressively perpendicular, due to its strong perpendicular magnetic anisotropy, leading to a resistance increase. At low field values, the magnetization of the thicker film tends to become perpendicular to the film plane and parallel to the magnetization of the thinnest Co film under the combined effect of small perpendicular anisotropy and ferromagnetic interlayer coupling. An additional complexity is brought by a small perpendicular field component and the large coercivity of the thinnest Co film which gives rise to the MR hysteresis. The MR versus field curve of Fig. 9 is strikingly similar to that observed by George *et al.* on (Fe/Cr/Fe)/Cu/Fe multilayers in which intrinsic inverse GMR at low fields is superimposed to normal GMR at higher fields.⁸

In conclusion, inverse GMR has been clearly observed in simple trilayers, FeV/Au/Co grown on Au(111). Alloying Fe with V has a qualitative effect on the spin scattering process, leading to a change of the asymmetry parameter from $\alpha > 1$ to $\alpha < 1$. The detailed MR dependence on the FeV layer thickness reveals a competition between interface scattering which gives normal GMR and bulk scattering responsible for the observed inverse GMR. It should be interesting to improve the knowledge of the thin FeV layers by microscopic

techniques such as x-ray magnetic circular dichroism and to investigate MR in multilayers including other Fe alloys such as FeCr and FeTi.

***Ab initio* calculations of spin-dependent transport properties (invited)** **(abstract)**

I. Mertig

TU Dresden, Institut für Theoretische Physik, D-01062 Dresden, Germany

Ab initio calculations of transport properties for ferromagnetic dilute alloys and magnetic multilayers are reported. The electronic structure of the considered system is calculated within the frame of density functional theory using local spin density approximation. The scattering of the electrons by impurities is described self-consistently by means of the Green function of the perturbed system. As a result the spin anisotropy of the scattering can be discussed without any free parameter. The transport is described quasiclassically, that is, the linearized Boltzmann equation is solved taking into account the anisotropy of the Fermi surface and the anisotropy of electron-impurity scattering. The method is applied to calculate the residual resistivity of dilute ferromagnetic Fe and Co alloys which are in very good agreement with experiment. Giant magnetoresistance (GMR) was computed for Fe/Cr multilayers for CIP (current in plane) and CPP (current perpendicular to plane) geometry. It can be shown that GMR exists for spin-independent scattering (Fe impurities in Cr layers) determined by the electronic structure of multilayers in ferro- and antiferromagnetic configuration. The consideration of spin-dependent scattering (say Cr impurities in Fe layers) enhances or reduces the GMR effect in dependence of the spin-anisotropy. It can be shown especially that combination of defects with different spin-anisotropy can produce inverse GMR. Finally, calculations are presented for GMR in granular Cu(Co) systems. From the investigation becomes obvious, that the effect is strongly influenced by the spin anisotropy of scattering. © 1996 American Institute of Physics. [S0021-8979(96)60508-4]

Optimizing the giant magnetoresistance of symmetric and bottom spin valves (invited)

We have attempted to optimize the values of the giant magnetoresistance in symmetric spin valves of the type NiO/Co/Cu/Co/Cu/Co/NiO (achieving 23.4%) and in bottom spin valves of the type Co/Cu/Co/NiO (achieving 17.0%), the largest values ever reported for such structures. The key elements in this achievement are improved vacuum conditions and careful attention to the film thicknesses. © 1996 American Institute of Physics. [S0021-8979(96)53408-3]

I. INTRODUCTION

Symmetric¹ (or dual²) spin valves are important in the field of giant magnetoresistance (GMR) because they offer the possibility of achieving large GMR values in magnetic multilayers which exhibit relatively low saturation fields. To put the issues in context, it is helpful to note that GMR values as large as 80% have been achieved in Co/Cu superlattices but at the cost of very large saturation fields, e.g., ~ 1 T, or 10^4 Oe.³ Saturation fields as low as 0.2 mT, or 2 Oe, have been reported for simple spin valves (containing only one Cu film), but the GMR of such structures is only 3%.⁴ Symmetric or dual spin valves represent an intermediate case (with two Cu films). Figure 1 illustrates a symmetric spin valve typical of those investigated in the present work. Also illustrated is one type of simple spin valve, a so-called bottom spin valve,¹ which may be viewed as the lower part of a symmetric spin valve.

The term bottom spin valve refers to the location of the pinning film, here NiO, which is at the bottom of the spin valve. In more conventional spin valves, the pinning film of FeMn is at the top.⁵ The NiO in the structures of Fig. 1 pins the adjacent magnetic films in a different manner than does FeMn. The FeMn acts by providing an exchange bias, whereas the NiO acts by inducing a very large coercivity in the adjacent Co film. In the bottom spin valve, the top Co film is unpinned and free to switch magnetically at relatively low fields. In the symmetric spin valve the top and bottom Co films are pinned and the central Co film is free.

Symmetric spin valves might be expected to have substantially larger GMR values than simple spin valves because significantly longer electron mean free paths (MFPs) should be possible (perhaps through the entire five-film structure) for spin-allowed conduction paths when the Co films are magnetically in a parallel alignment state. However, in the antiparallel alignment state, symmetric spin valves should

exhibit short MFPs just as simple spin valves or superlattices do.

The goal of the present work is to achieve the largest GMR values possible in symmetric spin valves and bottom spin valves. A comparison of the resulting values should help to put on a quantitative basis the magnitude of the advantage that can be gained by the symmetric spin valve concept.

II. EXPERIMENT

The NiO substrates used in this work were polycrystalline films ~ 50 nm thick, deposited on 3 in. Si wafers by reactive magnetron sputtering at the University of California at San Diego and the University of Minnesota.⁶ At the National Institute of Standards and Technology, the wafers were cleaved into ~ 1 cm² squares, cleaned ultrasonically, rinsed, dried, and installed in the deposition chamber. The base pressure before depositing a spin valve was typically 2×10^{-8} Torr ($\sim 2 \times 10^{-6}$ Pa) of which $\sim 95\%$ was H₂ and the remainder primarily H₂O (as indicated by a mass spectrometer). The presence of H₂ during deposition has no apparent effect on spin valve properties unless the partial pressure exceeds $\sim 10^{-6}$ Torr. The base pressure is achieved partly by depos-

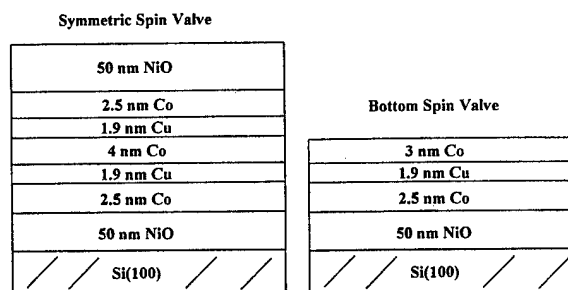

FIG. 1. An illustration of the symmetric spin valve and bottom spin valve structures typical of those investigated in the present work.

^{a)}Dept. of Chemical Engineering and Materials Science.

^{b)}Dept. of Electrical Engineering.

iting a ~ 1.5 nm Ti film on the inside of the deposition chamber from a centrally mounted Ti filament just prior to deposition of each spin valve.

A base pressure of 3×10^{-10} Torr was achieved after baking the chamber overnight at 150°C , but this base pressure was degraded sharply when films were deposited by magnetron sputtering. During magnetron sputtering the walls of the chamber are bombarded by energetic electrons, atoms, and ions which desorb gases from the walls and degrade the vacuum. The best base pressure achievable within an hour after deposition of a symmetric spin valve was typically in the high 10^{-9} Torr region, even in a baked chamber. Thus, with the passage of time and with the deposition of many symmetric spin valves both a baked and an unbaked chamber converge on a base pressure of $\sim 10^{-8}$ Torr. Part of the problem is that some H_2O is formed from H_2 and O_2 during the deposition of the top 50 nm of NiO in a symmetric spin valve. However, even after repeated deposition of bottom spin valves (no NiO deposited) the base pressure was still no better than the low 10^{-9} Torr range.

The magnetoresistance (MR) measurements were made *in situ* at room temperature (RT) using the four-point probe dc mode. Several symmetric spin valves were checked *ex situ* in two separate facilities and were found to have the same MR values. The bottom spin valves did not appear to be affected by exposure to background gases during the MR measurements. However, exposure to O_2 did produce significant effects, as discussed below.

It is very important to remove the hydrocarbon contamination (several tenths of a nanometer, which accumulates on the NiO from exposure to the laboratory air) prior to the deposition of each spin valve in order to achieve strong pinning and the largest GMR values. Samples were sputtered with a neutralized-beam Ar-ion gun at a beam energy of 100 eV until the carbon was removed (as judged by *in situ* x-ray photoelectron spectroscopy). Ion beam energies of several hundred eV gave reduced pinning and GMR values, probably due to damage of the NiO surface. The metal films were deposited at RT by dc-magnetron sputtering in 2 mTorr Ar at a rate of ~ 0.1 nm/s. The top NiO film was deposited by sputtering a Ni target with an 85/15 mixture of Ar/ O_2 .

III. RESULTS AND DISCUSSION

A. Symmetric spin valves

In a previous publication,⁷ we presented our initial studies of symmetric spin valves. We found that the largest GMR values occurred in samples with film thickness values typical of those illustrated in Fig. 1. We also reported the dependence of GMR on the thickness of the Co films and on the sample temperature.

Subsequently, the most interesting result we have obtained on symmetric spin valves is the dependence of the GMR on the partial pressure of H_2O in the chamber just prior to deposition of the structure. The results are presented in Fig. 2 and indicate that the largest GMR values are obtained for the lowest H_2O partial pressures. Moreover, we find no indication that the GMR values are saturating at the lowest H_2O partial pressures we can reach.

FIG. 2. A plot of the GMR values obtained for symmetric spin valves of the type illustrated in Fig. 1 as a function of the partial pressure of H_2O in the chamber just prior to deposition.

It should be emphasized that the H_2O partial pressures just prior to spin valve deposition in Fig. 2 are probably somewhat lower than the partial pressures during spin valve deposition. The presence of the sputtering gas (2 mTorr of Ar) prevents such a measurement during deposition. Nevertheless, during spin valve deposition, the partial pressure of H_2O and other contaminant gases is probably higher than just prior to deposition. This likely increase is due to the desorption of atoms and molecules from walls of the chamber by the impact of the energetic electrons, atoms, and ions produced by the magnetron sputtering process. In general, we find that immediately after the Ar has been pumped out following the deposition of a spin valve, the H_2O partial pressure is higher than just before deposition. (Note here that H_2O pumps away more slowly than Ar due to its tendency to stick to the walls.) This increase is about a factor of 2 for bottom spin valves and about a factor of 5 for symmetric spin valves (deposition of the final NiO film by reactive sputtering apparently synthesizes some H_2O). Therefore, although the values of H_2O partial pressure plotted in Fig. 2 are not the actual pressures during spin valve deposition, they are probably a reasonable indication of the relative H_2O partial pressures during deposition.

The results of Fig. 2 are important because most laboratories make GMR spin valves in deposition systems for which the base partial pressure of H_2O is considerably higher than the best we can achieve. Typically, base pressures are $\sim 10^{-7}$ Torr, and H_2O is the primary component. The implications of Fig. 2 are that lower partial pressures of H_2O in the system should lead to significant increases in the GMR and that efforts to improve base pressures would be worthwhile for most laboratories.

It is possible that H_2O is not the contaminant responsible for the loss of GMR in Fig. 2, but it is the most likely candidate. As discussed in Sec. II, the chamber contains predominantly H_2 at the base pressure. However, the H_2 partial pressure is then typically around $\sim 10^{-8}$ Torr and one must introduce $\sim 10^{-6}$ Torr of H_2 into the chamber during deposition to produce a noticeable reduction of GMR in these samples (i.e., more than the usual $\pm 10\%$ scatter in the data). Another contaminant in the chamber is CO, which typically has a partial pressure a factor of ten lower than that of H_2O ,

FIG. 3. Magnetoresistance loops for the symmetric spin valve with the largest GMR ($\Delta R/R$) for (a) high fields and (b) low fields, recorded after saturation in a negative field (see arrows). The cross in (b) marks the center of the loop, which is shifted from zero field due to the coupling between the center Co film and the top and bottom Co films. (Note: 0.01 T=100 Oe.)

and could possibly make a contribution to the GMR reduction. The ratio of CO and H₂O partial pressures does not change much because our primary method of varying the H₂O partial pressure is the length of the pumpdown time since the last exposure of the chamber to air. The H₂O partial pressure is also modified by the deposition of spin valves and by the deposition of Ti films, but the ratio of CO and H₂O partial pressures is approximately constant. Other contaminants in the chamber typically have partial pressures at least a factor of five less than CO and are probably unimportant.

The mechanism for the reduction in GMR in Fig. 2 is not known, but one possibility is impurity scattering of conduction electrons by oxygen-atom impurities. The sheet resistance (in a saturation field) of the samples used for the data in Fig. 2 increases from 21.5 $\Omega/\text{sq.}$ to 28 $\Omega/\text{sq.}$ as the GMR drops from 23.4% to 3.1%.

Another possible contribution to the drop in GMR is a weakening observed in the strength of the pinning of the top Co film by the top NiO. This weakness indicates that the magnetization of the top and center Co films are never completely antiparallel.

Figure 3 presents the high-field and low-field GMR loops for the sample with a GMR of 23.4%, the largest value we achieved. The shape of the high-field loop in the Fig. 3(a) is explained by the top and bottom Co films being pinned by the adjacent NiO so that they exhibit large coercivities. The center Co film has a small coercivity and switches from parallel to antiparallel to produce the increase in resistance found in the center of the high-field loop (see arrows). The general shape of this loop is typical for simple spin valves which employ magnetic films of differing coercivity.⁸

FIG. 4. A plot of the GMR vs the thickness of the Cu films for symmetric spin valves of the type illustrated in Fig. 1.

In the low-field loop in Fig. 3(b), little change occurs in the magnetization of the top and bottom Co, and only the center Co film is switched. Note that the high-field loop exhibits a weak tail extending out beyond 0.1 T (1000 Oe) so that the GMR of the low-field loop is only 19.2%. The weak tail is likely due to some grains in the polycrystalline NiO strongly pinning small patches of Co in random directions so that a large field is required for complete parallel alignment.

Figure 4 shows the strong dependence of the GMR on the thickness of the Cu films (the dependence on the Co film thicknesses was published in Ref. 7). The steep increase in GMR with decreasing Cu thickness is a strong motivation to investigate novel methods of deposition that will permit the use of thinner Cu films in these structures. The impediment to thinner Cu films is that the ferromagnetic coupling of the center Co film to the top and bottom Co films rises very sharply for Cu thickness less than about 1.8 nm so that complete antiparallel alignment cannot be attained and the GMR drops. This coupling is attributable partly to magnetostatic "orange peel" coupling caused by interfacial roughness,⁹ and partly to the well-known oscillatory exchange coupling.¹⁰ In recent work, we have investigated the correlation between the surface roughness during spin valve deposition, as observed by *in situ* scanning tunneling microscopy, and the coupling strength.¹¹ Although that work was primarily based on glass and aluminum oxide substrates, a brief examination of spin valves deposited on NiO substrates found general similarities in grain size (~ 10 nm) and roughness (0.5–0.9 nm).¹¹

We are presently investigating various approaches to reducing the ferromagnetic coupling, including deposition at low substrate temperatures to suppress interdiffusion at the Co/Cu interfaces and the use of surfactants such as In, Pb, and Au to smooth the Co and Cu surfaces during deposition. These studies will be the subject of future publications.

The thermal degradation of our spin valves by prolonged annealing at 250 °C is the subject of other publications. See Ref. 12.

B. Bottom spin valves

Bottom spin valves do not appear to have any important performance advantages over symmetric spin valves. Nevertheless, it was useful to investigate their properties since some interesting insights have emerged.

FIG. 5. A plot of the GMR (in vacuum) vs the top Co film thickness for bottom spin valves of the type illustrated in Fig. 1 (the bottom Co film thickness is 2.5 nm). The effect of exposing the 3 nm Co sample to $\sim 10^{-2}$ Torr s of O_2 is also plotted.

The GMR loops of bottom spin valves generally have a very similar appearance to those of symmetric spin valves, e.g., Fig. 3. The principal difference is that the GMR is significantly smaller for bottom spin valves. Minor differences are often noted in the coercivity and coupling exhibited by the unpinned Co film, and they are generally slightly smaller for the bottom spin valves.

Figure 5 presents the dependence of the GMR on the thickness of the top Co film. The GMR is a maximum for a Co thickness of about 2.5–3.0 nm of Co. The results here are quite different from those for the center Co film of a symmetric spin valve (see Ref. 7), where the GMR exhibited a maximum for a center Co film thickness of about 3.0–5.0 nm of Co. One possible explanation for the bottom spin valve requiring less Co in the unpinned or “valve” film would be that some conduction electrons reflect specularly at the Co/vacuum interface. Note that specular reflection at this interface would increase the effective thickness of the Co.¹³

Also of interest in Fig. 5 is the effect of exposure to O_2 . We have consistently found that when the thickness of the top Co is close to its optimum value, a small additional increase in GMR can always be obtained by exposure of the sample to O_2 . It was found by x-ray photoelectron spectroscopy that the top two or three atomic layers of Co are readily oxidized, but as the surface oxidizes it becomes passivated, and O_2 exposures larger than $\sim 10^{-2}$ Torr s have little additional effect. The mechanism for the increase in GMR is not known, but one possibility is that an increase occurs in the amount of specular scattering (i.e., Co/CoO interface might scatter a larger fraction of the incident electrons specularly than does the Co/vacuum interface). Note here that specular scattering (as opposed to diffuse scattering) has the effect of allowing an electron to travel farther (in the direction of the current).

The GMR of 17.0% found after the exposure to O_2 (Fig. 5) is the largest value ever reported for a simple (one Cu film) spin valve. However, a disadvantage of this treatment is that the coercivity of the unpinned Co film increases from 3.5 to 5.4 mT (35 to 54 Oe).

This increase in coercivity represents the initial stage of the pinning process that occurs when a NiO film is deposited

FIG. 6. A plot of the GMR (in vacuum) vs the bottom Co thickness for bottom spin valves of the type illustrated in Fig. 1 (the top Co film thickness was 3 nm).

on Co (as in a symmetric spin valve). The NiO film is deposited after 2 mTorr of an 85/15 Ar/ O_2 mixture is introduced into the chamber and the Ni magnetron gun is turned on. Two or three atomic layers of Co will oxidize under these conditions before any NiO is deposited. Thus, CoO is actually in contact with the top Co film in a symmetric spin valve. We have attempted to increase the pinning of the top Co film in symmetric spin valves by depositing a few atomic layers of Ni on the Co prior to NiO deposition to prevent formation of the CoO, but so far no increases in the pinning have been achieved. The rationale for these attempts was that NiO has a much higher Néel temperature than CoO.

The maximum GMR without the use of O_2 is 16.2% (in Fig. 5). This value should be compared with the maximum GMR of 23.4% achieved for symmetric spin valves. The increase from 16.2% to 23.4% appears to be representative of the degree of improvement that can be expected in going from a simple spin valve to a symmetric spin valve.

The dependence of the GMR on the thickness of the bottom Co film, shown in Fig. 6, is quite different from that of the top Co film (in Fig. 5). Perhaps the most surprising result is that a mere 1 nm of Co gives a respectable 11.3% GMR. This result is surprising because conductivity measurements indicate that 1 nm Co is near the percolation threshold, and a very patchy film is likely.

Figure 7 presents the coercivity of the bottom (pinned) Co film as a function of its thickness. If the pinning is purely due to the underlying NiO, i.e., if there is no contribution from the Co itself, a $1/t$ dependence would be expected as thicker Co provides a larger lever arm, as it were, to rotate the magnetization. The solid line in Fig. 7 is a $1/t$ extrapolation from the largest Co thickness backwards to smaller values. The fit is quite good down to 2 nm. Below 2 nm it appears that a different effect is occurring. The coercivity appears to be dropping sharply, as illustrated by the dashed line. This drop is presumably associated with the Co film becoming discontinuous.

Figure 8 presents the dependence of the coercivity and the coupling of the top Co film on its thickness. The scatter in the data prevents identification of the functional dependence but the coupling decreases roughly as $1/t$ (the solid

FIG. 7. A plot of the coercivity of the bottom Co film vs its thickness for bottom spin valves. See the text for explanations of the solid and dashed curves. (Note: 10 mT=100 Oe.)

curve), and the coercivity increases roughly linearly (the dashed curve) with Co thickness. From all points of view, the bottom spin valve properties are clearly optimized with a top Co thickness of 2.5–3 nm.

IV. CONCLUSIONS

The major conclusions of this work may be summarized as follows:

- (1) The GMR of symmetric spin valves increases strongly as the partial pressure of H_2O in the chamber prior to film deposition decreases.
- (2) The GMR increase in symmetric spin valves shows no sign of saturating at the lowest H_2O partial pressures obtainable in the present work, $\sim 10^{-9}$ Torr.
- (3) The largest GMR value obtained for a symmetric spin valve in this work is 23.4% at RT.
- (4) The largest GMR value obtained for a bottom spin valve is 17.0% at RT.
- (5) There are some indications that specular scattering of conduction electrons may occur at Co/vacuum and Co/CoO interfaces and may increase the GMR slightly.

We used the Layer Korringa Kohn Rostoker technique to calculate the electronic structure of cobalt-copper multilayers and spin valves from first principles within the local spin density approximation. Using this electronic structure together with a phenomenological self-energy which may vary from layer to layer, we calculated the non-local layer-dependent conductivity by means of the Kubo linear response formalism. By calculating the majority and minority conductivities for parallel and anti-parallel alignment of the moments in the cobalt layers we determined the giant magnetoresistance (GMR). Several interesting features emerge from the calculations. When the scattering rates are relatively high, we find that the contributions to the GMR are largely non-local, with the largest contributions arising from changes in the currents carried in a cobalt plane next to copper due to fields sensed in the cobalt layer on the other side of copper. When scattering rates are relatively low (comparable to that of cobalt and copper at room temperature), there are important contributions to the GMR from local conduction in the copper layers. This effect arises from the fact that when the component of the majority spin electron momentum parallel to the layers exceeds a certain value, it gets trapped in the copper layers. If the scattering rate is lower in the copper than in the cobalt there is a significant enhancement in the majority spin conductivity and in the GMR. This effect is analogous to the channeling of light by an optical waveguide. © 1996 American Institute of Physics. [S0021-8979(96)79508-1]

I. INTRODUCTION

A new form of magnetoresistance called “giant” magnetoresistance (GMR) was discovered in 1988.^{1,2} GMR is a change in the electrical resistance of an inhomogeneous system that is observed when an applied magnetic field causes an alignment of the magnetic moments in different parts of a material. This phenomenon has aroused considerable interest because it can be used to make magnetic field sensors and because it gives valuable insight into spin dependent transport.

GMR has been observed in several geometries, but the GMR systems that have aroused the greatest interest for magnetic sensor applications are composed of extremely thin layers of ferromagnetic material separated by non-magnetic or very weakly magnetic spacer layers. Two geometries are particularly attractive. One is the “spin valve” geometry which consists of two ferromagnetic layers separated by a non-magnetic spacer layer.³ The magnetic moment of one of the ferromagnetic layers is pinned by exchange coupling to a hard anti-ferromagnet while the other is relatively free to rotate with an applied field. The other geometry is a (more or less) periodic multilayer consisting of alternating ferromagnetic and non-magnetic spacer layers. For the multilayer geometry, one depends on the moments in alternate ferromagnetic layers having an anti-parallel alignment in the absence of an applied field.

The transport properties of layered materials have been the subject of previous theoretical investigations, most of which have used the model of free electrons with random

point scatterers (FERPS). References to most of this work may be found in a recent review.⁴

In this paper we report on first-principles calculations of the transport properties of Co|Cu multilayers and Co|Cu|Co spin valves. The electronic structure of these systems is calculated self-consistently using the local spin density approximation to density functional theory. We then use this electronic structure to calculate the conductivity by evaluating the Kubo-Greenwood linear response formula. Our calculations reveal two new effects that are important for GMR, a “resonance” effect and an electron channeling effect. The latter effect is analogous to the channeling of light by an optical waveguide.

II. NON-LOCAL CONDUCTIVITY OF FREE ELECTRONS, COPPER, AND COBALT

When an electromotive force is applied to a material, a local applied electric field, $E_\nu(\mathbf{r})$, is created which induces currents, $J_\mu(\mathbf{r})$. The linear, non-local coefficient relating the current to the applied field is the conductivity $\sigma_{\mu\nu}(\mathbf{r}, \mathbf{r}')$,

$$J_\mu(\mathbf{r}) = \int d\mathbf{r}' \sum_\nu \sigma_{\mu\nu}(\mathbf{r}, \mathbf{r}') E_\nu(\mathbf{r}'). \quad (1)$$

Thus, $\sigma_{\mu\nu}(\mathbf{r}, \mathbf{r}')$ is the current in direction μ at point \mathbf{r} induced by an applied field of unit magnitude applied at the point \mathbf{r}' . This non-local conductivity is given by^{5,6}

$$\sigma_{\mu\nu}(\mathbf{r}, \mathbf{r}') = \pi \hbar \langle j_\mu \text{Im} G(E_F; \mathbf{r}, \mathbf{r}') j'_\nu \text{Im} G(E_F; \mathbf{r}', \mathbf{r}) \rangle, \quad (2)$$

FIG. 1. Non-local layer dependent conductivity parallel to the planes for free electrons, copper, cobalt majority and cobalt minority. For free electrons and for copper, the Fermi energy is chosen so that the Fermi surface contains 0.5 electrons/atom-spin.

where j_μ is the current operator $(-ie\hbar/m)\partial/\partial r_\mu$, and the imaginary part of the Green function arises from a sum over the exact eigenstates of the system. The angular brackets in Eq. (2) indicate a configurational average.

In this paper we consider systems which consist of stacks of atomic planes. Although these planes may differ, we assume that they have a common underlying two-dimensional periodicity. We find it convenient and instructive to calculate the non-local conductivity, $\sigma_{\mu\nu}(I, J)$

which is the current in direction μ in atomic plane I due to an applied electric field of unit magnitude in direction ν applied in atomic plane J . $\sigma_{\mu\nu}(I, J)$ is given in terms of the non-local conductivity $\sigma_{\mu\nu}(\mathbf{r}, \mathbf{r}')$ by integrating over the atomic cells in plane J and averaging over the atomic cells in plane I ,

$$\sigma_{\mu\nu}(I, J) = N_I^{-1} \sum_i \sum_j \Omega_j^{-1} \int_{\Omega_i} d\mathbf{r} \int_{\Omega_j} d\mathbf{r}' \sigma_{\mu\nu}(\mathbf{r}, \mathbf{r}'). \quad (3)$$

Here N_I is the number of cells in plane I and Ω_j is the volume of an atomic cell in plane J . The sums run over the cells in planes I and J , respectively.

For the FERPS model of a *homogeneous* system, the non-local *layer dependent* conductivity obtained by dividing space into artificial atomic planes can be obtained analytically.⁷ The conductivity is determined by the Fermi energy and by the imaginary part of the self-energy which is the scattering rate, $\text{Im } \Sigma / \hbar = 1/(2\tau)$. The non-local layer dependent conductivity parallel to the layers for free electrons with one electron per atom and a density corresponding to copper is shown in Figure 1. The scattering rate, $\text{Im } \Sigma$, is taken to be 0.005 Hartree ($= 0.136$ eV). The non-local conductivity shown in the figure is the contribution to the current in layer I parallel to this layer due to a field applied in the same direction in layer J . The layers are slabs, 0.208 nm in thickness corresponding to the thickness of {111} atomic planes in copper. The Fermi Energy is 7.058 eV correspond-

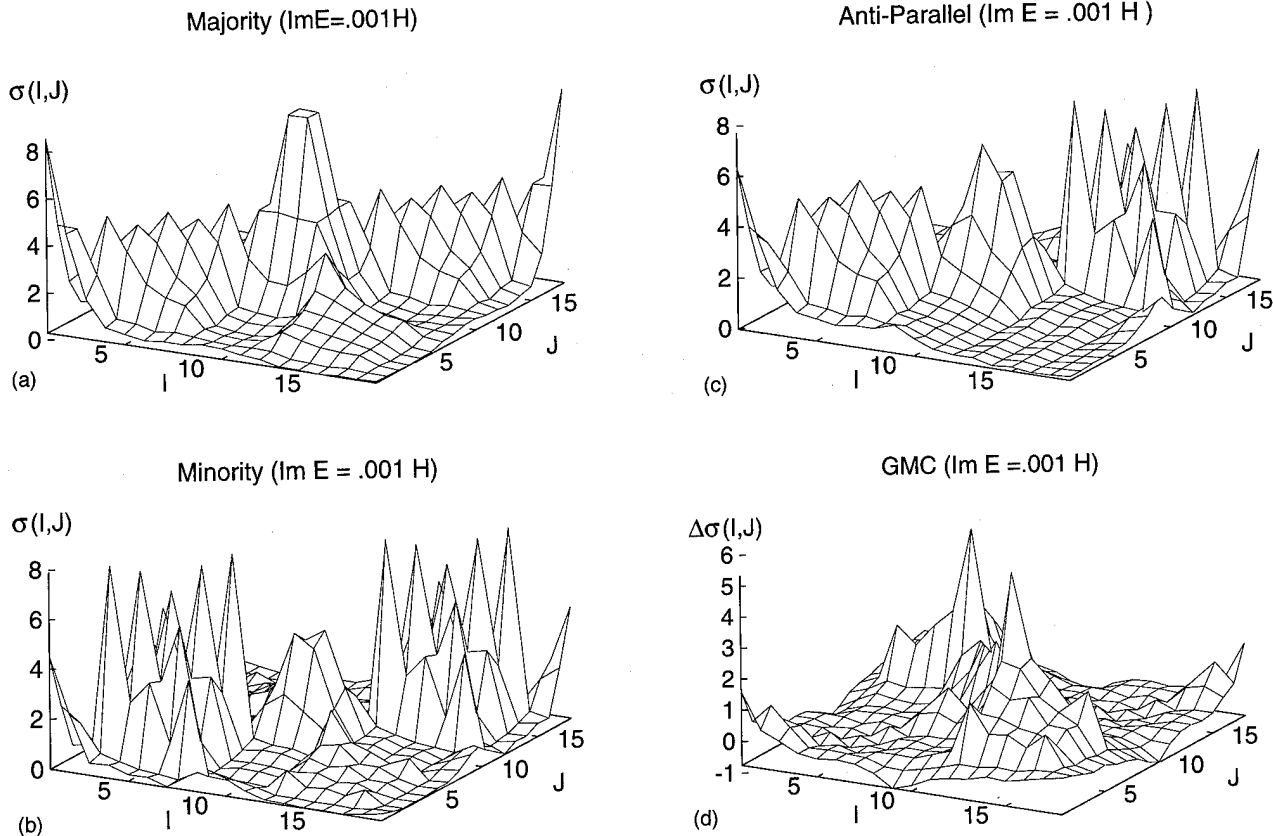

FIG. 2. Non-local dependent conductivity for a periodic Co_3Cu_4 multilayer: (a) majority spin conductivity for moments aligned, (b) minority spin conductivity for moments aligned, (c) majority spin conductivity for moments anti-aligned, and (d) change in conductivity of both spin channels between aligned and anti-aligned configurations of moments.

FIG. 3. Cuts through Fermi surfaces of bulk copper, majority bulk cobalt, and majority Fermi surface of a periodic Co_5Cu_4 (111) multilayer. The labels $\bar{\Gamma}$ and \bar{K} refer to points at the center and corners, respectively, of the hexagonal two dimensional Brillouin zone. The points labeled Γ , L , and K refer to symmetry points in the three dimensional Brillouin zone. k_{\parallel} and k_{\perp} are expressed in units of $2\pi/a$, where a is the fcc lattice constant.

ing to 0.5 electrons/spin. The conductivity is given in units of $10^{15}/\text{s}$. This conductivity can be converted to a resistivity in $\mu\Omega \text{ cm}$ by dividing it into 898.8. The sum of $\sigma(I, J)$ over I or J gives the total conductivity for this homogeneous system.

These non-local layer dependent conductivities for free electrons can be compared with similar quantities which we calculated for copper and cobalt. The techniques which we have developed for calculating non-local layer dependent conductivities from the Kubo formula have been described previously.⁸⁻¹¹ Figure 1 also shows the calculated values of the non-local layer dependent conductivity, $\sigma_{xx}(I, J)$, for copper and for cobalt at their respective Fermi energies using the same scattering rate of 0.005 Hartree (0.136 eV). The atomic planes were again taken to be perpendicular to the $\{111\}$ direction.

It can be seen from Figure 1 that the non-local conductivity of copper perpendicular to the $\{111\}$ direction resembles that of free electrons although the overall conductivity is less and the mean free path (roughly the inverse of the slope of the non-local conductivity curve) is less than for free electrons with the same scattering rate. The non-local conductivity of majority cobalt also resembles that of free electrons although the differences are greater. It appears that there are fewer carriers in majority cobalt and that they have more

than one mean free path. These results are consistent with our knowledge of the electronic structure of copper and cobalt. The copper Fermi surface contains 0.5 electrons/spin channel but its conductivity is reduced from that of free electrons with the same scattering rate because the Fermi velocities are lower. The conductivity of majority cobalt is lower still because its volume is smaller and its velocities are lower due to a larger admixture of d -character.

The Fermi energy for the minority spins lies within the d -bands and is quite complicated with multiple sheets. The band velocities are low over most of the cobalt minority Fermi surface but the surface area is sufficiently large that that the total minority conductivity is approximately the same as the majority conductivity if the scattering rates are the same. The character of the conductivity is different, however, it is much more localized in space, hence the more rapid decay of the non-local conductivity of minority cobalt in Figure 1.

III. NON-LOCAL CONDUCTIVITIES OF PERIODIC MULTILAYERS AND SPIN VALVES

We have calculated the electronic structure and the non-local conductivity of periodic multilayers consisting of 5 $\{111\}$ atomic planes of cobalt alternating with 4 $\{111\}$ atomic planes of copper. This system was chosen because it is similar to the one for which a very large GMR, $\Delta\rho/\rho > 0.35$, was observed¹² at room temperature. The stacking was assumed to be fcc for all of the layers. A uniform scattering rate, $\text{Im } \Sigma = 0.001 \text{ Ha}$, was assumed for all layers and for both spin channels. Figures 2(a) and 2(b) show results of these calculations for the majority and minority channels respectively for the case in which all of the cobalt moments are aligned. Figure 2(c) shows the non-local conductivity for one of the channels for the case in which alternate layers of cobalt have their moments anti-aligned. Figure 2(d) shows the difference for the total non-local layer conductivity in both channels between the aligned and anti-aligned cases. The figures show $\sigma_{xx}(I, J)$ where x is a direction parallel to the $\{111\}$ planes. The arrangement of the atomic planes as shown in the figures is $\text{Cu}_2|\text{Co}_3|\text{Cu}_4|\text{Co}_5|\text{Cu}_2$, periodically repeated. Thus atomic planes, I or $J = 1, 2, 8-11, 17$ and 18 are copper, while atomic planes $3-7$ and $12-16$ are cobalt.

The majority channel conductivity for aligned moments, Figure 2(a), shows several interesting effects. The non-local conductivity in the cobalt layers is largest for $|I - J| = 0$ and falls off similarly to its behavior in bulk cobalt if both I and J are cobalt layers. $\sigma(I, J)$ for I a cobalt layer drops when J enters the copper region, but it then *increases* when J enters the second cobalt region. This surprising effect lies outside a simple FERPS model and is a major contributor to the GMR. For brevity, we shall refer to this effect as the "resonance" effect since we suspect that it is caused by the similarity of the wave functions and energy levels on different cobalt layers. A similar but smaller effect can be seen between copper layers and between cobalt layers in the minority channel.

The most striking feature of Figure 2(a) is the large conductivity localized on the copper layers. The values of non-

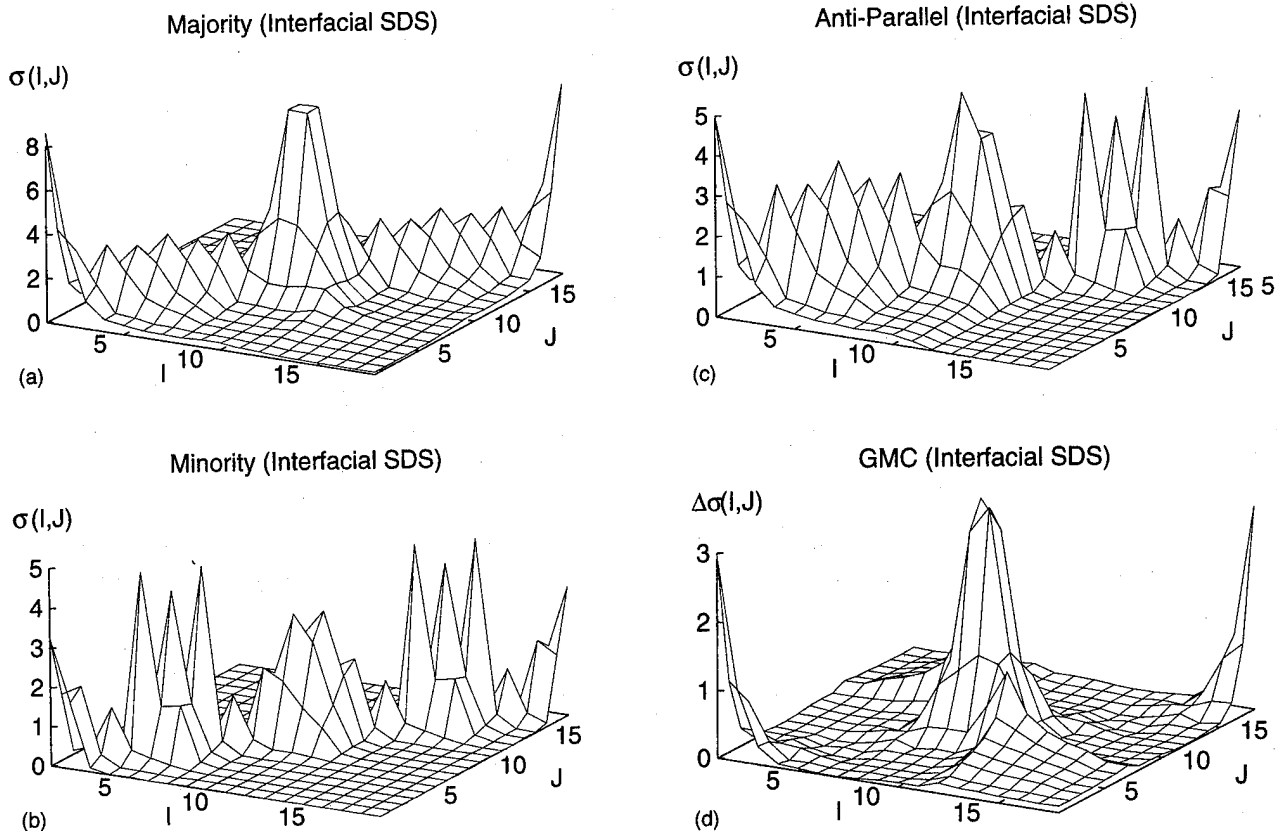

FIG. 4. Non-local layer dependent conductivities assuming different scattering rates in the copper and cobalt layers and different scattering rates for majority and minority spin cobalt: (a) majority spin conductivity for parallel alignment of cobalt moments, (b) minority spin conductivity for parallel alignment of cobalt moments, (c) conductivity for anti-parallel alignment, (d) giant magnetoconductance.

local conductivity $\sigma(I, J)$ when I and J are both in the same copper layer are larger than they would be in bulk copper. This surprising enhancement of the local conductivity in the copper is due to an electron channeling effect. Figure 3 shows cuts through the Fermi surfaces of copper, majority cobalt, and majority Co_5Cu_4 along the direction $\bar{\Gamma} \rightarrow \bar{K}$ in the two dimensional Brillouin zone. This cut also includes the points Γ , K , and L of the three dimensional zone. We can see that for values of k_{\parallel} between approximately 0.6 and 0.74, there is a valid value of k_{\perp} for copper but not for majority cobalt. For most directions in the two dimensional zone, there is a similar region where k_{\perp} is allowed for copper but not for majority cobalt. Thus, when Co and Cu are combined to make the multilayer, Co_5Cu_4 , one or more majority bands will split off that are relatively dispersionless in k_z when viewed as a function of k_{\parallel} . The majority Fermi surface of Co_5Cu_4 is also shown in Fig. 3. The bands responsible for the electron channeling are the essentially vertical lines near $k_{\parallel} = 0.65$ and 0.705 . The fact that a single value of k_{\parallel} corresponds to all values of k_{\perp} indicates that the electrons corresponding to this band are localized perpendicular to the layers. Examination of the wave functions indicates that they are localized on the copper layers. The complicated cobalt minority Fermi surface provides valid values of k_{\perp} for essentially all values of k_{\parallel} for which there are valid values of k_{\perp} in copper. Thus, there is no channeling of minority electrons in copper.

Electrons can also be channeled within the cobalt layers. From Figure 3 it is clear that there is a region near $k_{\parallel} = 0$ for which there are allowed values of k_{\perp} in majority cobalt but not in copper. This leads to electrons being "trapped" in the cobalt, but the effect is much smaller than channeling within the copper layers because only a small portion of the Fermi surface is involved.

Figure 2(d) shows the contributions to the giant magnetoconductance, i.e., the difference between the conductivity of both channels for the moments aligned and the conductivity of both channels with the moments anti-aligned. For this case in which the scattering rate is the same on all layers and for both spins, we see that the resonance effect makes the primary contribution to the GMR. The GMR obtained by summing over the contributions shown in Figure 2(d) is $\Delta\sigma/\sigma_{AP} = 0.13$.

The calculations represented by Figures 2(a)–2(d) assumed a constant scattering rate for all atomic planes and both spins. We have performed an analogous set of calculations assuming a scattering rate in the copper that is appropriate to room temperature copper, and which assumes differing scattering rates for the majority and minority cobalt spins. The cobalt scattering rates were fixed by the known room temperature resistivity of cobalt and the assumption that the majority and minority scattering rates in the cobalt are proportional to their Fermi energy state densities. The results of these calculations are shown in Figures 4(a)–4(d).

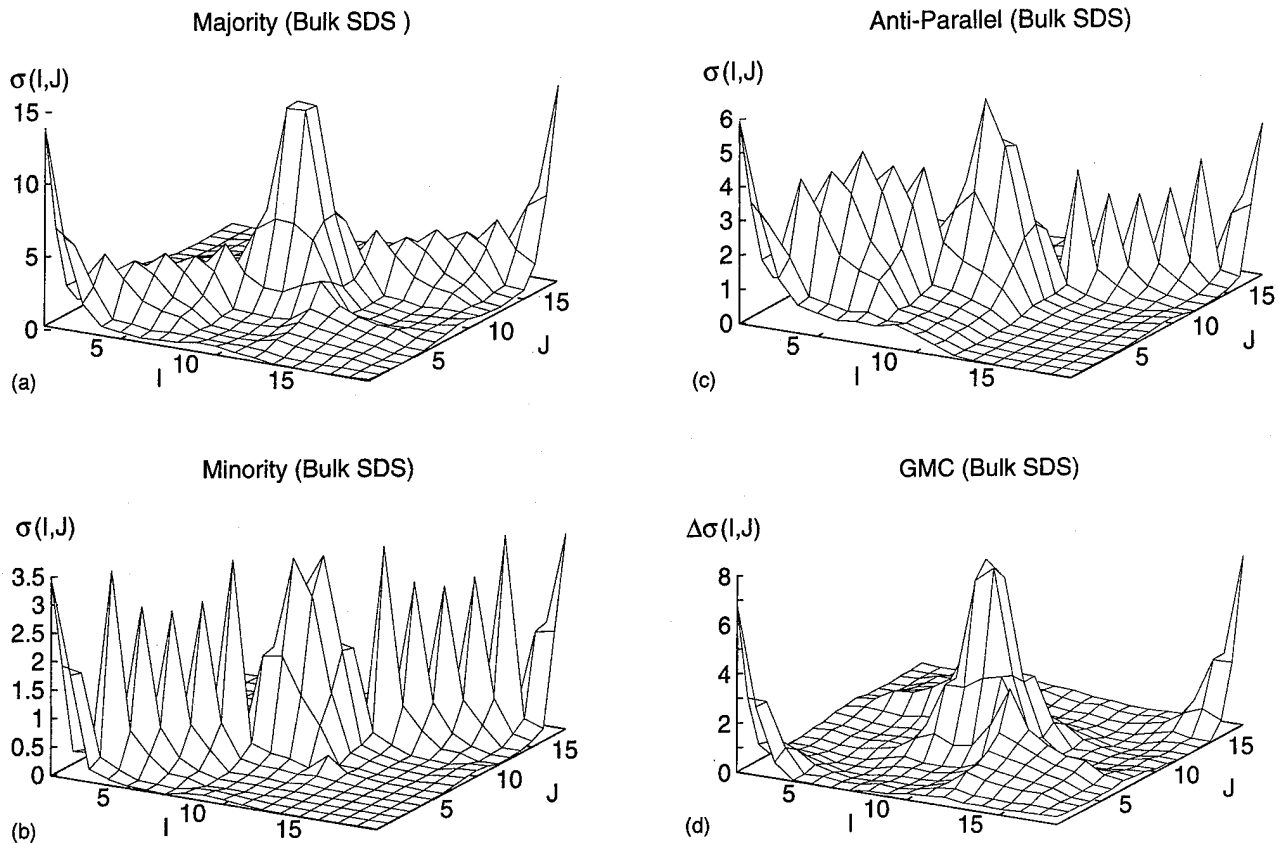

FIG. 5. Calculated non-local layer dependent conductivities for the case of strong interfacial scattering: (a) majority spin conductivity for parallel alignment, (b) minority spin conductivity for parallel alignment, (c) majority spin conductivity for anti-parallel alignment, (d) giant magnetoconductance.

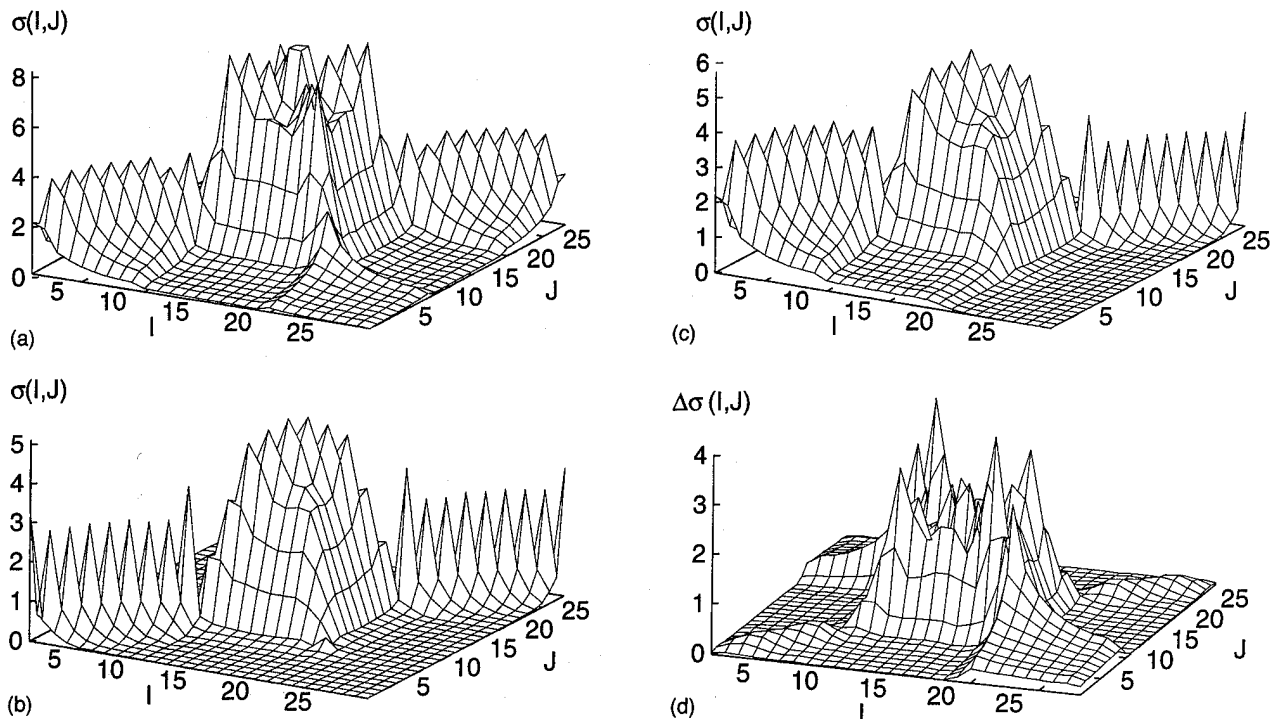

FIG. 6. Non-local layer dependent conductivities for a spin valve: (a) majority spin conductivity, (b) minority spin conductivity for parallel alignment, (c) majority spin conductivity for anti-parallel alignment, (d) giant magnetoconductance.

An enhancement of the local conductivity in the copper for the majority electrons due to electron channeling is seen similarly to the case of uniform scattering rates. In this case, the form of the giant magnetoconductance is quite different. There are large contributions involving a single copper layer. Thus electron channeling greatly increases the majority conductivity even when the scattering is spin and species independent, but when the scattering is stronger in the cobalt than in the copper it can have a large effect on the GMR as well. The GMR obtained by summing over the contributions shown in Figure 4(d) is $\Delta\sigma/\sigma_{AP}=0.43$.

In addition to assuming a constant scattering rate and one in which the bulk scattering rates in the cobalt differ, we also considered the possibility that the scattering rates on the cobalt planes are the same for majority and minority spin channels and that there is strong spin-dependent scattering near the interfaces. Such strong spin dependent scattering is quite plausible if there is intermixing between the cobalt and copper in the interfacial layers. Specifically, we assumed that the scattering rate in the cobalt was $\text{Im } \Sigma = .0025 \text{ Ha}$ for both majority and minority cobalt and that the scattering rate in the copper was $\text{Im } \Sigma = .0006 \text{ Ha}$. On the interfacial cobalt planes we assumed scattering rates of .005 Ha for the majority channel and .06 Ha for the minority channel. The factor of 12 difference in scattering rates is based on CPA calculations for cobalt with copper impurities. On the interfacial copper planes scattering rates of .002 Ha and .005 Ha were assumed for the majority and minority channels, respectively. The calculated non-local conductivities are shown in Figures 5(a)–5(d). The increased conductivity in the copper layers due to electron channeling is evident. The GMR obtained by summing over the contributions shown in Figure 6(d) is $\Delta\sigma/\sigma_{AP}=0.22$.

We have also calculated the electronic structure and non-local conductivity of cobalt-copper spin valves. The electronic structure of these spin-valves has been described previously.¹¹ Figure 6 shows the calculated non-local conductivity of a spin valve consisting of 10 atomic {111} copper planes with 10 {111} cobalt planes (with fcc stacking) on either side. We assume the same scattering rates as for the periodic multilayer of Figure 4. A strong enhancement of the conductivity in the copper layers is evident for the majority electrons and parallel configuration. Figure 6(d) shows that there are strong contributions to the GMR from both the resonance effect evidenced by the peak when I and J are in different cobalt layers and from the channeling effect evidenced by the peak when both I and J are in the copper layer. The GMR obtained for this spin valve was $\Delta\sigma/\sigma_{AP}=0.26$.

IV. ORIGINS OF GMR IN COBALT-COPPER MULTILAYERS AND SPIN VALVES

Our first principles calculations illustrate two quite different effects which may be important sources of the large giant magnetoresistance that is seen in cobalt-copper multilayers and spin valves. The first of these mechanisms may be described as a tunneling or resonance effect and is character-

ized by a surprising peak in the non-local conductivity between two neighboring ferromagnetic layers compared to the conductivity between one of the ferromagnetic layers and the neighboring spacer layer.

The second mechanism is electron channeling which is quite analogous to the channeling of light by an optical waveguide. The channeled electrons have an interesting mode structure which we hope to describe elsewhere. The channeling effect does not seem to lead to a dramatic increase in the GMR if all scattering rates are the same. However, if there are different scattering rates in the cobalt and in the copper, the effects of channeling on the GMR can be quite spectacular. This suggests strategies for increasing the GMR which we shall discuss elsewhere. It also raises the question of whether or not interfaces in current GMR systems are so rough that the channeling effect is killed by diffuse scattering at the interface.

The possibility of electron channeling has been noted previously by Hood and Falicov¹³ who treated the semiclassical FERPS model and by Vedyayev *et al.*¹⁴ who used the quantum FERPS model.

Phenomena of colossal magnetoresistance (MR) or magnetic field induced insulator-metal ($I-M$) transitions have been investigated for single crystals of perovskite-type manganese oxides with controlled carrier density and one-electron bandwidth. In addition to the canonical MR behavior near the Curie temperature, the first-order phase transition accompanying several orders of magnitude change in resistivity has been observed under an external magnetic field for many of the composition-controlled crystals as an intrinsic bulk phenomenon. It was proved by the systematic experimental investigations that the field-induced destruction of the charge-ordered state accompanying the lattice structural as well as metamagnetic transition is a major origin of such a colossal MR. Versatile MR phenomena and $I-M$ phase diagrams in the $T-H$ plane are presented with their interpretation. © 1996 American Institute of Physics. [S0021-8979(96)53508-X]

I. INTRODUCTION

Large magnetoresistance (MR) near the Curie temperature in perovskite-type manganese oxides is of current interest, but was readily reported in 1969 by Searle and Wang¹ for a flux-grown crystal of $\text{La}_{1-x}\text{Pb}_x\text{MnO}_3$. Soon after, Kubo and Ohata² presented the theoretical calculation based on the Kondo-lattice model with ferromagnetic coupling, which could give an essential account for the large MR observed near the Curie temperature T_c . More recently, however, unusually large MR was found in thin films^{3,4} and single crystals⁵⁻⁹ of various perovskite-type manganese oxides $\text{RE}_{1-x}\text{AE}_x\text{MnO}_3$ (RE and AE being trivalent rare earth and divalent alkaline earth ions, respectively), which cannot be accounted for in terms of the simple double-exchange mechanism. On the basis of the experimental investigations on the high-quality single crystals with accurately controlled compositions, we propose here that the charge-ordering phenomenon as well as its collapse under an external field is a key to understanding of such a colossal magnetoresistance (CMR).

The charge ordering in pseudocubic and layered perovskite manganites^{5,10-15} has been assigned to the real space ordering of e_g electrons with the $(\pi, \pi, 0)$ pattern, i.e., the alternating $\text{Mn}^{3+}/\text{Mn}^{4+}$ sites on the (001) plane and hence tends to be most stabilized at the nominal hole concentration $x=0.5$. The charge-ordering accompanies, in general, a change (0.04%–2%) in lattice parameters, yet the transition temperature T_{CO} does not always coincide with the spin-ordering (or orbital-ordering) critical temperature: in some cases T_{CO} is higher than the Néel temperature T_N but in other cases lower than the Curie temperature T_c , as shown later in detail. The relative stability of the charge-ordered (CO) state to the ferromagnetic state mediated by the double-exchange interaction critically depends on the lattice form (or the tolerance factor of the crystal) as well as on the nominal hole concentration x .

II. ELECTRONIC PHASE DIAGRAM

We show in Fig. 1 electronic phase diagrams in the temperature (T)–hole concentration (x) plane for prototypical compounds: $\text{La}_{1-x}\text{Sr}_x\text{MnO}_3$ (left), $\text{Pr}_{1-x}\text{Sr}_x\text{MnO}_3$ (middle), and $\text{Pr}_{1-x}\text{Ca}_x\text{MnO}_3$ (right). As the tolerance factor or equivalently the average ionic radius of the perovskite A site decreases from (La,Sr) to (Pr,Ca) through (Pa,Sr), the orthorhombic distortion of the GdFeO_3 -type increases, resulting in the bending of the Mn—O—Mn bond and hence in the decrease of the one-electron bandwidth of the e_g -state carriers.¹⁶ This means that other electronic instabilities, such as the charge-ordering and superexchange interactions, which compete with the double-exchange interaction may become dominant in specific x and temperature regions.

The phase diagram for $\text{La}_{1-x}\text{Sr}_x\text{MnO}_3$ ¹⁷⁻¹⁹ is canonical as the double-exchange system. The Jahn–Teller distorted end compound LaMnO_3 undergoes the phase transition to the spin-cant phase below $x=0.1$.²⁰ With further doping, the fer-

FIG. 1. The magnetic as well as electronic phase diagrams for $\text{La}_{1-x}\text{Sr}_x\text{MnO}_3$ (left) (Refs. 17–19), $\text{Pr}_{1-x}\text{Sr}_x\text{MnO}_3$ (middle) (Ref. 5), and $\text{Pr}_{1-x}\text{Ca}_x\text{MnO}_3$ (right) (Refs. 6 and 8). PI, PM, and CI denote the paramagnetic insulating, paramagnetic metallic, and spin-canted insulating states, respectively. FI and FM denote the ferromagnetic insulating and ferromagnetic metallic states, respectively. For $0.3 \leq x \leq 0.5$ in $\text{Pr}_{1-x}\text{Ca}_x\text{MnO}_3$, the antiferromagnetic insulating (AFI) and canted antiferromagnetic insulating (CAFI) states exist in the charge-ordered (COI) state.

romagnetic metallic phase appears below T_c which steeply increases with x up to 0.3 and then saturates. The temperature dependence of resistivity above T_c is insulating or semiconductive for $x < 0.3$, which may be interpreted in terms of the carrier localization arising from some random potential or electron-phonon coupling (e.g., dynamic Jahn-Teller effect²¹). The ferromagnetic insulating (FI) phase is present in a fairly narrow x region ($x = 0.10-0.17$), in which the double-exchange carrier is subject to localization (Anderson localization) but can still mediate the ferromagnetic interaction between the neighboring sites and realize the ferromagnetic state in a bond-percolation manner.

Such a ferromagnetic but insulating region becomes expanded as the tolerance factor is decreased: The low-temperature ferromagnetic phase is insulating up to $x = 0.3$ for $\text{Pr}_{1-x}\text{Sr}_x\text{MnO}_3$ (Ref. 5) and $\text{Pr}_{1-x}\text{Ca}_x\text{MnO}_3$ (Refs. 6 and 8) as seen in Fig. 1. For the former compound, the ferromagnetic metallic (FM) phase shows up for $x \geq 0.3$, yet in the immediate vicinity of $x = 0.5$ the insulating CO phase sets in below $T_{\text{CO}} = 140$ K. For $\text{Pr}_{1-x}\text{Ca}_x\text{MnO}_3$ with a further reduced tolerance factor, the CO phase is present below 220–240 K for $x \geq 0.3$ and no FM phase shows up in any x region at zero field. In the CO phase of this compound, there are successive magnetic transitions to the charge-ordered antiferromagnetic insulating (AFI) phase and to the charge-ordered spin-canted insulating (CAFI) phase.^{10–13} An observed variation of the transition temperatures T_N and T_{CA} with x can be interpreted in terms of the partial revival of the double-exchange carriers in the CO phase: The CO pattern is always $(\pi, \pi, 0)$ in the pseudocubic setting irrespective of x and hence the deviation of x from $x = 0.5$ may produce extra carriers which play a role of modifying the spin structure as observed. Such a discommensuration of the nominal hole concentration seems to affect not only the temperature-dependent spin structure but also magnetoresistance and metal-insulator phase diagram in the T - H plane as discussed below.

III. FIELD-INDUCED MELTING OF CHARGE-ORDERED STATE

In the perovskite-type manganites the resistivity near T_c is much reduced by applying an external field, since the field forcedly aligns the t_{2g} local spins and hence the double-exchange carriers gain a mobility due to a reduced spin scattering. This is typically seen in temperature dependence of resistivity for $\text{La}_{1-x}\text{Sr}_x\text{MnO}_3$ ($x = 0.175$, $T_c = 284$ K)¹⁸ shown in Fig. 2 (left). Incidentally, the resistivity anomaly around 220 K is due to the rhombohedral-orthorhombic structural transition and its transition temperature is also affected by an external field (see Ref. 22 for details of this novel phenomenon).

Such a resistivity change near T_c is also observed for $\text{Pr}_{1-x}\text{Sr}_x\text{MnO}_3$ ($x = 0.5$, $T_c = 250$ K) as shown in Fig. 2 (middle). However, a more remarkable field effect for this compound is seen upon the CO phase transition associated with a large resistivity change.⁵ At zero field, the metallic resistivity shows an abrupt jump at $T_{\text{CO}} = 150$ K due to the onset of the CO phase (see also Fig. 1). The CO transition temperature appears to be decreased with increasing field and

FIG. 2. Temperature dependence of resistivity under magnetic fields for $\text{La}_{1-x}\text{Sr}_x\text{MnO}_3$ ($x = 0.175$, left) (Ref. 18), $\text{Pr}_{1-x}\text{Sr}_x\text{MnO}_3$ ($x = 0.5$, middle) (Ref. 5), and $\text{Pr}_{1-x}\text{Ca}_x\text{MnO}_3$ ($x = 0.35$, right) (Ref. 8).

above 7 T the insulating CO phase is totally extinguished over the whole temperature region. The phenomena may be viewed as a field-induced melting of the generalized Wigner crystal.

For $\text{Pr}_{1-x}\text{Ca}_x\text{MnO}_3$ where the CO state dominates over the double-exchange FM state in the fairly wide x region, a much higher field (about 30 T at 4.2 K) is needed for destruction of the CO state at $x = 0.5$.²³ However, the deviation of x from 0.5 (discommensuration) brings about a drastic modification in the field-induced I - M transitions. We show in Fig. 2 (right) the temperature dependence of the resistivity for the $x = 0.35$ crystal under various fields.⁸ The CO transition manifests itself as a steep rise of the resistivity at $T_{\text{CO}} = 230$ K. Contrary to the case of $\text{Pr}_{1-x}\text{Sr}_x\text{MnO}_3$ ($x = 0.5$), the field-induced I - M transition takes place from a low-temperature side with increase of field. In other words, under a magnetic field (e.g., below 10 T) the FM state positions at lower temperature than the CO state while vice versa for $\text{Pr}_{1-x}\text{Sr}_x\text{MnO}_3$. The measurement of the magnetization⁶ as well as the neutron scattering study¹³ under a field proved that the field-induced insulator-metal (I - M) transition is accompanied by the metamagnetic (spin-canted antiferromagnetic to ferromagnetic) transition as well as the collapse of the CO state.

The isothermal magnetoresistance (MR) shown in Fig. 3 also clearly indicates the collapse of the CO state under a field, showing a field-induced I - M transition or the so-

FIG. 3. Isothermal magnetoresistance for $\text{Pr}_{1-x}\text{Sr}_x\text{MnO}_3$ ($x = 0.5$, left), $\text{Nd}_{1-x}\text{Sr}_x\text{MnO}_3$ ($x = 0.5$, middle) (Ref. 7) and $\text{Pr}_{1-x}\text{Ca}_x\text{MnO}_3$ ($x = 0.35$, right) (Ref. 8). Hatches indicate the hysteretic field regions.

FIG. 4. The electronic phase diagrams in the T - H plane for $\text{Pr}_{1-x}\text{Sr}_x\text{MnO}_3$ ($x=0.5$, left) (Ref. 5), $\text{Nd}_{1-x}\text{Sr}_x\text{MnO}_3$ ($x=0.5$, middle) (Ref. 7) and $\text{Pr}_{1-x}\text{Ca}_x\text{MnO}_3$ ($x=0.35$, right) (Ref. 8).

called CMR. Reflecting the first-order nature of the CO transition (associated with a change in lattice parameters), the isothermal MR for $\text{Pr}_{1-x}\text{Sr}_x\text{MnO}_3$ ($x=0.5$) in Fig. 3 (left) shows a temperature-dependent hysteresis against the field. The hysteretic field region seems to be gradually expanded with decrease of temperature. Such a first-order nature is more clearly seen for $\text{Nd}_{1-x}\text{Sr}_x\text{MnO}_3$ ($x=0.5$)⁷ with a smaller tolerance factor: the hysteretic field region at lower temperature is expanded and even covers those at higher temperatures as indicated by different hatches in Fig. 3 (middle).

The isothermal MR for $\text{Pr}_{1-x}\text{Ca}_x\text{MnO}_3$ ($x=0.35$) is shown in Fig. 3 (right).⁸ The resistivity at relatively low temperatures (say, below 40 K) shows a conspicuous change from an insulating value above $10^7 \Omega \text{ cm}$ to a typical metallic value ($3 \times 10^{-4} \Omega \text{ cm}$) exceeding ten orders of magnitude. The hysteretic field region is expanded with lowering temperature and the field-induced I - M transition becomes even irreversible below 15 K, as exemplified by the MR curve at 4.2 K in Fig. 3 (right).

On the basis of the isothermal MR data, we have obtained the I - M phase diagram in the T - H plane (Fig. 4) for these prototypical compounds; $\text{Pr}_{1-x}\text{Sr}_x\text{MnO}_3$ ($x=0.5$, left), $\text{Nd}_{1-x}\text{Sr}_x\text{MnO}_3$ ($x=0.5$, middle), and $\text{Pr}_{1-x}\text{Ca}_x\text{MnO}_3$ ($x=0.35$, right). The respective I - M phase boundaries show the temperature-dependent hysteresis against field. The hysteretic field region (indicted by hatches in Fig. 4) is expanded with decrease of temperature, which gives rise to a peculiar shape of phase boundary for $\text{Nd}_{1-x}\text{Sr}_x\text{MnO}_3$ and $\text{Pr}_{1-x}\text{Ca}_x\text{MnO}_3$. This can be interpreted in terms of the suppression of thermal fluctuation effect for the first-order transition.^{7,8} The transition of a metastable state is essentially prohibited when thermal energy is much lower than the potential barrier height. The low-temperature metallic phase ("charge liquid" phase) in the T - H plane is thus a sort of supercooled state which is present even at lower temperatures below the "charge crystal" (CO) phase in the T - H plane. In particular, the metallic phase appears to invade toward the low-field region for $\text{Pr}_{1-x}\text{Ca}_x\text{MnO}_3$ ($x=0.35$). This seems to be closely correlated with the discommensuration of the CO state and the resultant change of the spin structure to the canted antiferromagnetic state which is more amenable to an external field than the antiferromagnetic state.

FIG. 5. Temperature dependence of resistivity under magnetic fields for $(\text{Nd}_{0.063}\text{Sm}_{0.937})_{1-x}\text{Sr}_x\text{MnO}_3$ ($x=0.5$, left) (Ref. 9), $\text{Sm}_{1-x}\text{Sr}_x\text{MnO}_3$ ($x=0.4$, middle) (Ref. 24) and $\text{Pr}_{1-x}\text{Ca}_x\text{MnO}_3$ ($x=0.3$, right) (Ref. 5) as examples of the striction-coupled first-order phase change to the ferromagnetic metallic state.

IV. STRICTION-COUPLED MAGNETORESISTANCE

The CO state is located above the FM state at a external field (<10 T) in the case of $\text{Pr}_{1-x}\text{Ca}_x\text{MnO}_3$ ($x=3.5$) as shown in Figs. 3 and 4. The CO transition is always accompanied more or less by a structural change and hence the CO-to-FM transition is of the first order in nature. For $\text{Pr}_{1-x}\text{Ca}_x\text{MnO}_3$ systems, such a phase transition is also seen for the $x=0.3$ crystal⁶ (left panel of Fig. 5) in which the CO transition is not so clearly discernible in the temperature dependence of resistivity but of magnetization and can be detected as a structural transition around 200 K.¹³ Due to the enhanced discommensuration from $x=0.5$, the low-temperature FM state is produced with a relatively low field, e.g., at 3 T for $\text{Pr}_{1-x}\text{Ca}_x\text{MnO}_3$ ($x=0.3$).

With fine tuning of the discommensuration and/or the tolerance factor, we can realize the first-order CO-to-FM transition with decrease of temperature even at zero field as exemplified in Fig. 5 (left and middle) for $(\text{Nd}_{0.063}\text{Sm}_{0.937})_{1-x}\text{Sr}_x\text{MnO}_3$ ($x=0.5$)⁹ and $\text{Sm}_{1-x}\text{Sr}_x\text{MnO}_3$ ($x=0.4$),²⁴ respectively. The former system is derived by further decreasing the tolerance factor (or the one-electron bandwidth) from $\text{Nd}_{1-x}\text{Sr}_x\text{MnO}_3$ while keeping the nominal hole concentration at a commensurate value ($x=0.5$). On the other hand, the latter system may be viewed as derived by increasing the tolerance factor from $\text{Pr}_{1-x}\text{Ca}_x\text{MnO}_3$ while maintaining the discommensuration from $x=0.5$. The inverse magnetization of these compounds shows a Curie-Weiss-like behavior above 250 K but a clear deviation with a slight upturn or plateau below 230–240 K down to T_c .⁹ Upon the transition to the FM state, a lattice structural change occurs and the resistivity shows a sharp drop by several orders of magnitude. These are reminiscent of the presence of the CO state above T_c but below 240 K as in the case of $\text{Pr}_{1-x}\text{Ca}_x\text{MnO}_3$ ($x=0.3$)^{6,13} under a magnetic field. The first-order transition from such a CO-like state to the FM state is quite sensitive to an external field as shown in Fig. 5 (left and middle). It was confirmed by magnetostriction measurements⁹ that the FM transition under a field is also accompanied by a structural change perhaps arising from the field-induced collapse of the CO state. Judging from the phase diagram for $\text{Pr}_{1-x}\text{Ca}_x\text{MnO}_3$ (left panel of Fig. 4), the FM state at low temperatures is mostly the metastable state

FIG. 6. Isothermal magnetoresistance for a $(\text{Nd}_{0.063}\text{Sm}_{0.937})_{1-x}\text{Sr}_x\text{MnO}_3$ ($x=0.5$) (Ref. 9) crystal in comparison with that for a $\text{La}_{1-x}\text{Sr}_x\text{MnO}_3$ ($x=0.17$) crystal near above the respective Curie temperature T_c .

which cannot decay to the thermodynamically stable state (perhaps the antiferromagnetic CO state) due to the aforementioned suppression of the thermal fluctuation at low temperatures.

Reflecting the first-order nature of the CO-FM transition at T_c , the striction-coupled MR shows a switching-like behavior near above T_c (113 K), as exemplified for $(\text{Nd}_{0.063}\text{Sm}_{0.937})_{1-x}\text{Sr}_x\text{MnO}_3$ ($x=0.5$) in Fig. 6. For comparison, the isothermal MR is also plotted for $\text{La}_{1-x}\text{Sr}_x\text{MnO}_3$ ($x=0.175$) near T_c . As compared with the conventional MR for this compound, the striction-coupled MR change for $(\text{Nd}_{0.063}\text{Sm}_{0.937})_{1-x}\text{Sr}_x\text{MnO}_3$ ($x=0.5$) is quite remarkable: The resistivity drop associated with the phase change is more than three orders of magnitude as seen in Fig. 5 and hence appears to reach nearly zero level in such a linear-scale plot as Fig. 6. The switching-like CMR is observed, though accompanied by the hysteresis (not shown in Fig. 6), even at a low field as far as the temperature is close to T_c . The phenomena may have potential for some application to magnetoswitching materials and devices.

V. CONCLUSION

We have briefly reviewed our recent studies on the CMR phenomena of perovskite-type manganese oxides with use of single crystals in which the tolerance factor and the nominal hole concentration are finely controlled. It was proved by the systematic investigation on the magnetotransport and related magnetic and structural properties that the collapse of the charge-ordered insulating state under an external field is closely correlated with the field-induced colossal change of resistivity accompanying a release of the striction. Both the

tolerance factor (or equivalently the one-electron bandwidth of the e_g carriers) and the nominal hole concentration x affect crucially the metal-insulator phase diagram in the T - H plane which is modified as a result of the competition between the double-exchange and charge-ordering interactions.

Colossal magnetoresistivity in manganese-based perovskites (invited) (abstract)

R. Ramesh, T. Venkatesan, S. B. Ogale, R. L. Greene, and S. M. Bhagat
Center for Superconductivity Research, University of Maryland, College Park, Maryland 20742

Magnetoresistivity values of the order of $10^6\%$ (and in some cases even higher) have been obtained in epitaxial $A_xB_{1-x}\text{MnO}_{3-y}$ ($A=\text{La}, \text{Nd}$; $B=\text{Ca}, \text{Sr}, \text{Ba}$) thin films grown by pulsed laser deposition. Ferromagnetic resonance experiments suggest a granular-type behavior with conducting ferromagnetic regions ($R_{\text{cond}} < 10 \text{ m}\Omega \text{ cm}$) in a less conducting matrix ($R_{\text{insulating}} > 100 R_{\text{cond}}$). Ion channeling experiments over a range of temperatures clearly reveal the existence of structural distortion at the peak resistivity temperature T_p . Systematic studies of samples prepared under a variety of oxygenation conditions show that the resistivity above T_p can be modeled with a single functional form: $R_{\text{cond}} \approx e^{\Delta/kT}$, where Δ , the activation energy, is of the order of 50–200 meV. This suggests that these different samples represent the same basic material in a semiconducting matrix, with differing volume fractions of the two components which depends on the processing conditions. These “colossal” values of MR have been obtained at temperatures lower than room temperature and at fields of the order of a few Teslas, both of which are impediments to the development of viable MR sensor and nonvolatile storage technologies. We are therefore addressing the critical scientific and technological issues through a variety of materials integration approaches. Using structural chemistry and lattice matching as fundamental guiding principles, we are growing epitaxial heterostructure superlattices consisting of the CMR oxides interleaved with magnetic perovskites such as La–Sr–Co–O (metallic ferromagnet), rare earth–Fe–O (ferromagnetic insulator). We are also exploring the possibility of using the semiconducting properties of these materials in an all-perovskite field effect transistor device. In this presentation, we will describe our progress to date on these studies to enhance the field and temperature dependence of the MR properties and explore new device architectures that utilize the inherently novel properties of these materials. © 1996 American Institute of Physics. Nanoparticles of Nd-Fe-B-C with their crystal structure similar to the $\text{Nd}_2\text{Fe}_{14}\text{B}$ phase were generated in a carbon arc. With an average diameter of less than 40 nm, they are monodomain. They have a smaller room-temperature coercivity than would be predicted from the bulk magnetocrystalline anisotropy. However, their coercivity is greater than was previously observed in particles $<5\text{ }\mu\text{m}$ prepared by spark erosion. While the carbon arc process is useful for making small carbon-coated particles which resist oxidation, here dispersion of excess Nd in the carbon matrix results in a significant paramagnetic signal. The dc demagnetization curves enable the paramagnetic and ferromagnetic contributions to be distinguished. © 1996 American Institute of Physics. [S0021-8979(96)40308-8]

I. INTRODUCTION

Fine particle magnetism has been an active field for many years.¹⁻³ Experimental support for this theory has been obtained for a variety of ferromagnetic fine particles.⁴ However, since this time there have been significant developments both in permanent magnet materials and in fine particle synthesis. Here we combine two of these breakthroughs, the high magnetocrystalline anisotropy alloy neodymium iron boron and the carbon arc process⁵ for preparing nanocrystals,⁶ and analyze the magnetic properties of the resulting monodomain particles.

Bulk neodymium iron boron magnets have the highest known energy product of any permanent magnet material.⁷ This ternary alloy is quite complex. Boron is present to stabilize the hard magnetic phase, tetragonal $\text{Nd}_2\text{Fe}_{14}\text{B}$.⁸ Sintered magnets frequently have a secondary α -Fe phase of approximately 10 nm thickness at the grain boundaries,⁹ which may be significant in the oxidation which plagues these materials. At low temperatures, bulk $\text{Nd}_2\text{Fe}_{14}\text{B}$ also undergoes a spin reorientation transition at 135 K.¹⁰ The magnetic properties of the related materials, $\text{Nd}_2\text{Fe}_{14}\text{B}_{0.5}\text{C}_{0.5}$ and $\text{Nd}_2\text{Fe}_{14}\text{C}$, have also been reported.¹¹

Several groups have prepared micron-sized particles of Nd-Fe-B alloys, by spark erosion in liquid argon,¹² by ball milling,¹³ and by heat treatment of metal and oxide powders.¹⁴ In all of these materials the particle sizes were on the order of microns, and they therefore contained multiple magnetic domains. The coercivities measured were significantly smaller than in the bulk material.

Monodomain particles of Nd-Fe-B-C are of interest to test the model of size-dependent coercivity.¹⁵ The maximum size for a single magnetic domain has been estimated at $\sim 200\text{ nm}$ for $\text{Nd}_2\text{Fe}_{14}\text{B}$.¹⁶ The carbon arc process has been

applied to a variety of metals and alloys to prepare nanoparticles in the 5–50 nm size range, well below the single domain threshold. The carbon coating of the nanoparticles is also an advantage in preventing oxidation. Cobalt particles made by this method have been boiled in sulfuric acid without reaction.¹⁷ We have recently demonstrated the use of electron spectroscopic imaging to obtain elemental maps on a nanometer scale,¹⁸ which could enable us to detect nanometer-scale phase separation in this alloy. With this new approach to synthesis and a new tool to characterize chemical inhomogeneity, we sought to understand the behavior of these monodomain magnets.

II. EXPERIMENT

Nanoparticles embedded in a carbon matrix were prepared by a variation of the Huffman–Krätschmer carbon arc process.⁵ To make the nanoparticles, a composite anode was made from graphite and 30 wt % Nd-Fe-B (Crucible, Inc.), with dextrin as a binder. Though this method has been used to prepare other materials with up to 70 wt % metal,¹⁹ a 30 wt % metal fraction was studied here. The composite anode was combined with a graphite cathode in a carbon arc (30 V dc, 100 A, 500 Torr He), and vaporized. The nanoparticles were collected as a powder from the reactor walls.

The nanoparticle morphology was determined through a combination of transmission electron microscopy (TEM) and x-ray diffraction (XRD) measurements on as-prepared and annealed powder samples. Electron spectroscopic imaging (ESI) of an annealed sample was done with a Gatan Imaging Filter attachment to a JEOL 4000 EX electron microscope. In this technique a combination of high-resolution imaging and electron energy loss spectrometry is used to generate elemental maps.

For magnetic measurements, the powders were dispersed in epoxy and placed in a Quantum Design SQUID magnetometer at fields between $\pm 5\text{ kOe}$ for temperatures ranging

FIG. 1. Left: TEM of carbon-coated Nd-Fe-B-C nanoparticles. Dark spheroidal regions are the nanoparticles and smaller spheres are part of the amorphous carbon matrix. Right: electron spectroscopic imaging of the same sample, showing the distribution of Nd. The corresponding Fe map shows that only the nanoparticles contain iron.

from 2 to 300 K. The diamagnetic contributions of the epoxy and carbon matrix were measured separately and subtracted from the magnetization data. Due to the possibility of additional paramagnetic contributions from Nd carbides, the dc demagnetization (DCD) curves²⁰ were also measured. Here the sample was first saturated and then subjected to an increasingly negative field. The remanent magnetization, M_r , is measured after the field is removed.

III. RESULTS AND DISCUSSION

The carbon arc process generated gram quantities of spherical nanoparticles well below the monodomain threshold. The particles were embedded in an amorphous carbon matrix, and followed a log-normal size distribution, with an average radius of 18.2 nm and a standard deviation of 1.9 nm.

The sample was annealed in argon for 12 h at 900 °C, without increasing the average particle size determined by TEM. Several x-ray diffraction peaks similar to those in the $\text{Nd}_2\text{Fe}_{14}\text{B}$ phase emerged: (410), 100%, $2\theta=42.4^\circ$; (411), 64%, 43.5° ; (314), 77%, 44.6° , though not all of the prominent features were detected. No evidence of $\alpha\text{-Fe}$, NdC_2 , or $\text{Nd}_3\text{Fe}_{20}\text{C}_x$ (Ref. 21) was observed. Nominal $\text{Nd}_2\text{Fe}_{14}\text{C}$ is actually a mixture of rhombohedral $\text{Nd}_2\text{Fe}_{17}\text{C}_x$ and $\alpha\text{-Fe}$,¹¹ and is inconsistent with our data. The most likely structure is an alloy similar to $\text{Nd}_2\text{Fe}_{14}\text{B}$, but containing a mixture of B and C.

Electron spectroscopic imaging was used to obtain Nd (Fig. 1) and Fe maps in an annealed sample. While the iron was localized within the nanoparticles, we found that Nd was distributed throughout both the particles and the matrix. In the matrix, it presumably took the form of NdC_2 or Nd_2C_3 clusters too small to be detectable by XRD. These species are paramagnetic and therefore contribute to the overall magnetization, but not to the remanence or coercivity. We saw no evidence of a Nd-deficient layer near the nanoparticle surface as found in the bulk material, or for a mixture of Nd-Fe and $\alpha\text{-Fe}$ phases. No oxygen was detected in these samples, verifying that the carbon coating protects the nanoparticles from oxidation. While this technique is extremely useful for measuring elemental abundances on a nanometer scale, this is not yet a quantitative technique. It could not be used to determine the exact stoichiometry, because the carbon signal

FIG. 2. Ordinary hysteresis loop for Nd-Fe-B-C nanoparticles, and dc demagnetization curve for the same sample.

could arise from either dissolved carbon in the nanoparticles or from the carbon coating which surrounds them.

The hysteresis loops for the Nd-Fe-B-C nanoparticles show coercivity even at room temperature (Fig. 2), but H_c is considerably smaller than would be predicted from the particle size and the room-temperature anisotropy of the bulk material. For a sample prepared from 30 wt % Nd-Fe-B starting material, $M_s=49.5$ emu/g, $M_r=14.2$ emu/g, and $H_c=830$ Oe at 5 K. The switching field distribution showed no indication of multiple phases with widely differing coercivities. The remanent magnetization dropped sharply with temperature up to approximately 45 K, and continued to drop more slowly up to room temperature. This contrasts with a maximum in the magnetization at ~ 100 K in bulk $\text{Nd}_2\text{Fe}_{14}\text{B}_{0.5}\text{C}_{0.5}$, which has a spin reorientation temperature of 128 K.¹¹

The difference between the saturation and remanent magnetizations is greater than the factor of two expected for random ordering, from the neodymium with a large paramagnetic contribution from the neodymium carbide clusters. DCD measurements (Fig. 2) showed similar values for M_r , but smaller values of M_s and larger values of H_c (1500 Oe at 5 K) because the paramagnetic contributions were absent. The magnetization reversal of the paramagnetic fraction before that of the ferromagnetic particles reduces the overall magnetization and shifts the field for which $M=0$, thereby reducing the measured coercivity. Efforts to model the DCD curves are underway.

FIG. 3. The dc demagnetization curve coercive field as a function of temperature. Fit to high-temperature data indicates an $(A-BT^{0.28})$ dependence, where A and B are constants.

In spherical particles of $\text{Nd}_2\text{Fe}_{14}\text{B}$, magnetocrystalline anisotropy is expected to dominate the shape anisotropy in determining the field required for magnetization reversal. Stoner–Wohlfarth theory² predicts that below the blocking temperature, T_B , the lowest temperature at which the coercivity equals zero, H_c will obey at $T^{1/2}$ power law. Experimentally we observe a $T^{0.28}$ dependence of the measured coercivity (Fig. 3) above 75 K and a $T^{0.17}$ dependence below it. Because the anisotropy energy density of bulk $\text{Nd}_2\text{Fe}_{14}\text{B}_{0.5}\text{C}_{0.5}$ changes sign at low temperature,¹¹ the Stoner–Wohlfarth model cannot be used to quantitatively interpret the results. A temperature dependence T^x with $x < 0.5$ has been observed in nanocrystalline materials with interacting grains, and here we may have some interactions between nanoparticles. Studies in lower abundance samples are underway.

IV. CONCLUSIONS

High coercivity monodomain nanoparticles of Nd-Fe-B-C in a carbon matrix have been prepared by the carbon arc process. Structural and chemical characterization indicates the presence of a phase similar to that of $\text{Nd}_2\text{Fe}_{14}\text{B}$, probably containing carbon. Neodymium was found to be dispersed throughout the carbon matrix, leading to a significant paramagnetic contribution to the magnetic results, and making dc demagnetization measurements essential for measuring the magnetic behavior of the nanoparticles. While the measured coercivity is greater than previously reported for micron-sized particles, it is still far below the value predicted from the bulk anisotropy energy density.

Submicron ferromagnets have been successfully incorporated into GaAs semiconductors by Mn^+ ion implantation and subsequent heat treatment. Transmission electron microscopy, x-ray fluorescence spectrum analysis, and atomic force microscopy are used to structurally characterize the GaMn precipitates which form within the GaAs matrix. These crystallites are room-temperature ferromagnets with controllable magnetic properties. Magnetic force microscopy images reveal that unmagnetized samples contain both magnetic dipoles and quadrupoles, but that after magnetization the single-domain state predominates. © 1996 American Institute of Physics. [S0021-8979(96)04708-6]

Spin-dependent phenomena seen in metallic multilayers and granular systems have raised basic questions about carrier magnetism and are currently finding technological applications.^{1,2} Effects such as giant magnetoresistance are highly desirable in semiconducting hosts, as such materials would offer great potential for exploring carrier spin scattering because the carrier densities are tunable through a wide range and their spatial confinement is easily controlled. These systems may then enable new magnetoelectronic and magneto-optical devices.³ To this end, we have successfully incorporated submicron room temperature ferromagnets into semiconductor materials by a simple process of ion implantation and subsequent heat treatment.⁴ Herein we present structural and magnetic characterizations of this new system.

The semiconductor samples are grown by molecular beam epitaxy (MBE) on semi-insulating GaAs substrates and consist of 500 nm undoped GaAs epilayers grown atop 50 nm AlAs and a 500 nm GaAs buffer. These structures are then uniformly implanted to depths of several hundred nanometers with Mn^+ ions at energies of 50 and 200 keV and doses ranging from 1×10^{14} to $5 \times 10^{16} \text{ Mn}^+/\text{cm}^2$. For comparison with MBE-grown materials, semi-insulating GaAs substrates are also implanted with comparable doses. To magnetically activate the implanted ions, the samples are covered with Si substrates and annealed in a forming gas (90% N_2 , 10% H_2) at temperatures from 600 to 920 °C for durations ranging from 5 s to 20 min. Both annealed and unannealed samples are thinned chemically and by ion milling for transmission electron microscopy (TEM) study. Electron microdiffraction and electron-beam-induced x-ray fluorescence spectroscopy are also employed for structural and compositional analysis. For magnetization measurements only, the GaAs substrate is removed to reduce the diamagnetic background. Etching the thin AlAs slab in diluted hydrofluoric acid⁵ releases the 500-nm-thick implanted surfaces from the substrate, and magnetization measurements of the resulting films are obtained from a rf SQUID magnetometer in fields up to 5 T and temperatures ranging from 5 to 400 K. Atomic force microscopy (AFM) and magnetic force microscopy (MFM) are employed at room temperature to spatially

probe both topography of the sample surfaces and the local magnetic fields generated by the submicron magnetic structures. Both unmagnetized and magnetized samples are studied by MFM in zero applied magnetic field. Furthermore, an electromagnet with fields up to 8 kOe enables MFM imaging in a variable magnetic field. Micromagnetic behavior of the submicron ferromagnets has been studied in applied magnetic fields and the results will be reported elsewhere.⁶

Figure 1(a) is a plan-view TEM micrograph taken on an

(a)

(b)

FIG. 1. (a) Plan-view TEM micrograph for a $1 \times 10^{16} \text{ Mn}^+/\text{cm}^2$ sample implanted at 200 keV and annealed at 920 °C for 60 s. (b) Electron-induced x-ray fluorescence spectrum taken on a single precipitate in (a). Semiquantitative analysis indicates that it contains 60% Ga and 40% Mn. The small As signal is from the GaAs substrate.

FIG. 2. SQUID magnetization data (300 K) of a $5 \times 10^{16} \text{ Mn}^+/\text{cm}^2$ sample annealed at 920°C for 60 s (the diamagnetic background has been removed). The inset shows the normalized remanent magnetization, $M(T)/M(5 \text{ K})$, as a function of temperature.

Mn^+ -implanted ($10^{16} \text{ ions/cm}^2$) and annealed (920°C for 60 s) GaAs sample. The dark spots seen in the picture are second phase precipitates which only appear in the annealed samples, whereas the dark streaks appearing elsewhere are strain-induced bend contours within the GaAs substrate. The precipitates are about 200 nm in diameter with an average separation of about $1.5 \mu\text{m}$. An x-ray fluorescence spectrum taken on one of these precipitates is shown in Fig. 1(b). Although a small As peak is present in this plan-view spectrum, similar spectra taken on precipitates in cross-sectional TEM samples show no As contribution, indicating that the As signal comes from the GaAs substrate only. Semi-quantitative compositional analysis indicates that the Ga:Mn atomic ratio is about 60:40. Cross-sectional TEM study⁴ of annealed samples reveals that GaMn precipitates pierce the implanted surface, enabling monitoring of precipitate formation by AFM.

Bulk magnetization measurements of the 500 nm implanted GaAs epilayers reveals room-temperature ferromagnetism. Figure 2 shows a magnetic hysteresis loop at 300 K arising from a sample implanted at $5 \times 10^{16} \text{ Mn}^+$ and annealed at 920°C for 60 s. The coercivity H_c is about 5 kOe at 300 K and is relatively insensitive to temperature. The inset shows remanent magnetization M_R (normalized at 5 K) as a function of temperature from 5 to 400 K. At 400 K, M_R drops to about 77% of its low-temperature value, implying that the Curie temperature is significantly higher than room temperature. In contrast, both (1) unimplanted and annealed and (2) implanted and unannealed controls are nonferromagnetic.

To study how this ferromagnetism develops throughout the annealing process, a series of implanted samples ($1 \times 10^{16} \text{ Mn}^+/\text{cm}^2$) is prepared under different annealing conditions. The resulting coercivities appear in Table I and show a peculiar trend. At the highest temperature of 920°C , longer annealing times result in lower coercive fields. Yet at an intermediate temperature of 800°C , longer annealing produces higher coercivities. Finally, at 600°C for 60 s, the hysteresis loop vanishes and the magnetization data can be fit to a Brillouin function. Results obtained from the Brillouin fit indicate that single or few spin complexes contribute to the paramagnetic behavior. The dependence of H_c on anneal-

ing conditions is not presently known, and may arise from changing crystalline structures (crystalline anisotropy) or from differences in interfacial strain between the GaMn precipitates and the GaAs substrate (strain anisotropy).

Room-temperature MFM measurements directly confirm that the ferromagnetism originates from the GaMn precipitates. Figure 3(a) is a topographic image of an area in a sample receiving $10^{15} \text{ Mn}^+/\text{cm}^2$, and Fig. 3(b) is a magnetic force image of the same area. The sample used for this imaging is unmagnetized and images are taken at zero applied magnetic field with a vertically magnetized Co-Cr coated tip. The bright and dark areas in Fig. 3(b) correspond to regions where the magnetic force acting on the MFM tip is repulsive and attractive, respectively. Although a one-to-one correspondence can be found between the two images, there are apparently three types of patterns in the magnetic force im-

FIG. 3. (a) Zero-field topographic and (b) magnetic force images of the same area on an unmagnetized $1 \times 10^{15} \text{ Mn}^+/\text{cm}^2$ sample annealed at 920°C for 60 s.

FIG. 4. Zero-field magnetic force image of the same area after the sample used in Fig. 3 is magnetized in a 2 kOe field outside of the MFM. The field applied is perpendicular to the sample surface.

age, indicative of different micromagnetic states. One type of pattern, appearing at particle "A" of Fig. 3(b), contains two bright-dark pairs. With a vertically magnetized MFM tip as used in this image, simulations of dipole-dipole interactions between tip and sample indicate that this type of pattern can only arise from a magnetic quadrupole. Another type of pattern, at "B," shows a relatively weak contrast. The sensitivity of our apparatus ensures that this signal is magnetic in nature, and the attractive interaction between the tip and these precipitates suggests a paramagnetic or superparamagnetic response to the stray field (~ 500 Oe) of the MFM tip. The third type of pattern, at "C" and "D," consists of two opposite magnetic poles and represents a magnetic dipole whose magnetic moment is not parallel to that of the MFM tip. Since the tip used for this imaging has been magnetized normal to the sample surface, symmetric bright-dark patterns as seen in "C" correspond to single-domain particles whose magnetic moment lies in the surface plane. Asymmetric patterns such as that in "D" correspond to single-domain precipitates with moments tilted out-of-plane.

A magnetic force image is obtained in the same area shown in Fig. 3 after removing the sample from the microscope, magnetizing it with the ~ 2 kOe stray field of a permanent magnet, and subsequently replacing it. Distinct differences can be found between the images of the unmagnetized and magnetized samples (Fig. 4). First, magnetic quadrupoles such as that previously seen at "A" have been converted to dipoles. The quadrupole-to-dipole conversion indicates that the single-domain state is a magnetically stable state for the submicron GaMn structures. Furthermore, this conclusion also holds for samples implanted with other doses. Second, the dipoles whose magnetic moments are initially at angles to the surface have switched to the field direction and appear as dark spots (e.g., "D"), while magnetic moments of the planar dipoles remain unchanged (e.g., "C").

Upon the application and removal of a magnetizing field, the moments of single-domain particles align with the field and relax into locally stable energy minima; they remain locked along easy axes after the field is removed. As described by the Stoner-Wohlfarth coherent rotation model,⁷ there is no hysteretic behavior for the particles with their easy axes perpendicular to the applied field, and thus, their moments will rotate back to the initial state after the vertical field is removed. Accordingly, we do not observe any change in contrast for planar magnetic moments, such as particle "C," after the sample is magnetized. A survey of larger areas in the magnetized sample shows that the easy axes of 80% of the GaMn particles align preferentially along three equivalent $\langle 001 \rangle$ directions of the GaAs substrate, as demonstrated in Fig. 4. However, we do not observe such preferential orientations in samples implanted with the highest dose. To study how a magnetic moment dynamically responds to a field for various easy axis orientations, we have constructed an electromagnet which can provide lateral magnetic fields up to 8 kOe while magnetic force imaging is performed *in situ*. Since the magnetic state of MFM tips also changes in lateral fields, it is impossible to interpret the actual images without knowing the response of the tip magnetization. We have used fine current strips as a magnetic field standard and obtained three components of the MFM tip magnetization vector vs. an applied magnetic field. The detailed micromagnetic study of MFM tips will be reported separately.^{6,8}

In summary, annealing crystallizes submicron GaMn ferromagnets within Mn^+ -implanted GaAs. Bulk magnetization measurements indicate that the Curie temperature of the GaMn precipitates exceeds room temperature. The coercivity of GaMn ferromagnets can be tuned over a wide range by varying annealing conditions. MFM measurements demonstrate that these magnetically stable submicron ferromagnets are single-domain particles with easy axes aligned preferentially along the $\langle 001 \rangle$ directions in magnetized lower dose samples.

Finite size effects in nanoscale Tb particles

D. Johnson, P. Perera, and M. J. O'Shea

Cardwell Hall, Department of Physics, Kansas State University, Manhattan, Kansas 66506-2601

Tb nanoscale particles are prepared in a matrix of Ti by sputtering. A range of samples are made with average particle diameter ranging from 1.5 to 21 nm. The magnetic transition temperature is depressed for smaller particles due to finite size effects. The coercivity at 4.5 K shows a maximum of 22 kOe at approximately 7 nm being a factor of 2.4 larger than a thick film of Tb. We compare the coercivity of our particle samples to multilayers of the form Tb/Mo and find larger coercivity in the particle systems due to the more confined geometry of the particles. © 1996 American Institute of Physics. [S0021-8979(96)04808-2]

We report a systematic study of the magnetic properties of nanoscale particles of the rare-earth Tb prepared in a matrix of Ti as a function of particle diameter. It has been known for some time that the magnetism of nanoscale particles is influenced by the presence of a large amount of interface and by their small (finite) size.¹⁻³ Our purpose here is to look at the influence of finite size and of a large amount of interface on magnetic properties of rare-earth systems where the intrinsic anisotropy is large. The intrinsic anisotropy of the rare earths is a single-ion anisotropy and derives from the large orbital angular momentum of the rare-earth ion. In bulk rare earths this large intrinsic anisotropy leads to a large hysteresis and a large coercivity.⁴

Tb is selected as the rare earth since it has one of the highest anisotropies of the rare earths⁴ and because its alloys tend to have the largest values of the magnetic transition temperature among the rare earths due to the large Tb spin ($S=3$) in the trivalent state.^{4,5} Ti is selected as the matrix since it has low solubility in Tb.⁶

The Tb particles are prepared in a matrix of Ti by dc Ar ion sputtering at a pressure of 5 mTorr on a Kapton substrate. Ti and Tb are alternately deposited. The Ti layers are 10 nm thick and the amount of Tb deposited is varied over an equivalent thicknesses t ranging from 0.4 to 8 nm. We find that for thinner equivalent thickness the Tb does not form a layer, rather it forms particles on the Ti layer. Two types of sample are prepared. The first samples are for electron microscopy studies and are trilayers of the form Ti(10 nm)/Tb(t nm)/Ti(10 nm), where t is the equivalent layer thickness of Tb deposited. The second samples are for magnetization studies and are of the form [Ti(10 nm)/Tb(t nm)] \times 20. Generally we find that the average particle diameter is a factor of 4 or 5 large than the equivalent layer thickness t and in the discussion below we only give the average particles diameter as measured by electron microscopy. Electron microscopy and magnetization samples are prepared in pairs one after the other during the same sputter run with the same value of equivalent Tb thickness t .

Transmission electron microscopy studies of the particle systems were done with a Philips 201 100 kV electron microscope. The Ti layer was thin enough at 10 nm that we were able to obtain reasonable contrast between the Tb particles and the background Ti matrix. The Tb particles show up as dark spots since they are more absorbing than the Ti background and they grow as more Tb is deposited. Figure 1

shows electron micrographs for two Ti/Tb/Ti samples and the dark Tb spots grow significantly when the amount of the Tb deposited is increased from 1.2 to 4.4 nm. The average particle diameters for these equivalent layer thickness are 5 and 13 nm, respectively. Figure 2 shows electron diffraction from a Ti/Tb/Ti sample and all the rings seen can be associated with either bulk hexagonal Tb or bulk hexagonal Ti lattice plane spacings. We have also done element specific real space imaging (through McCrone Associates) of Tb crystallites by selecting electron intensity from two Tb diffraction rings (within the ring shown in Fig. 2) and confirm the presence of particles and will report these results in more detail elsewhere. From electron microscopy measurements we find a range of particle sizes in each sample characterized by a standard deviation in particle diameter of about 30% of the mean particle diameter.

A thick homogeneous Tb film was also prepared on a

FIG. 1. Electron micrographs for Tb particle systems with average particle diameter of: (a) 5 nm, and (b) 13 nm. The equivalent layer thickness t deposited are 1.2 and 4.4 nm, respectively.

FIG. 2. Electron diffraction pattern for a Tb particle system with average particle diameter 13 nm.

Kapton substrate so that bulk properties (Curie-Weiss temperature T_0 , coercivity H_c) of sputtered Tb could be compared to properties of the particle samples. The Tb film thickness is 360 nm and it is coated with 20 nm of Ti to provide protection from oxidation. X-ray diffraction indicates that this film has the hexagonal structure of bulk Tb and is polycrystalline.

Figure 3 shows magnetization versus temperature for three particle samples. There are two curves for each sample corresponding to field-cooled magnetization (upper curve in each case) and zero-field-cooled magnetization (lower curve in each case). The largest particle systems show a magnetic transition temperature close to that of bulk Tb which is 230 K. As can be seen the particle samples have a depressed transition. Curie-Weiss plots ($1/\chi$ vs T) are done to determine the Curie-Weiss temperature T_0 and this is taken as a measure of the transition temperature. Figure 4 summarizes the variation of T_0 with average particle diameter. Below 10 nm T_0 decreases rapidly while above 10 nm it is close to the bulk value. Such a decrease is expected from the effects of

FIG. 3. Field-cooled and zero-field-cooled (upper and lower curves for each sample) magnetization at 200 Oe vs temperature for selected samples. Average particle diameter is given in nanometers. The lines are guides to the eye.

FIG. 4. Variation of transition temperature T_0 (upper panel) and coercivity at 4.5 K (lower panel) as a function of average particle diameter d .

finite size^{7,8} and has been seen in a number of transition metal multilayers,^{9,10} a rare-earth multilayer,¹¹ and in fine particle CuMn systems.³

All of the particle samples of this work show large hysteresis at low temperatures. Figure 5 shows magnetization curves for selected Tb particle samples. Figure 4 summarizes the coercivities of all the particle samples of this work and the coercivity shows a maximum for a particle diameter of about 7 nm. At large values of d , H_c approaches the bulk value (indicated in Fig. 4.) Such a maximum has been seen in coercivity versus particle diameter in other particle systems, e.g., Fe^3 , Fe_3O_4 ,^{12,13} and Fe-C ,¹⁴ but with a lower maximum coercivity.

It is expected that in isolated fine particle systems the coercivity H_c should depend on temperature as¹⁵

$$H_c = H_0(1 - \sqrt{(T/T_B)}), \quad (1)$$

where T_B is a blocking temperature to be determined and H_0 is a constant. We have measured H_c as a function of temperature in a number of our particle systems and an example is shown in Fig. 6 for a sample with average particle size 7 nm. The straight line represents a least squares fit of Eq. (1)

FIG. 5. Magnetization curves for selected Tb particle samples.

FIG. 6. Variation of coercivity with temperature for the particle sample with average particle diameter 7 nm.

to the data above 20 K and H_c follows the dependence of Eq. (1) in this regime. The fitted blocking temperature T_B is 190 K.

We have also looked at multilayers of Tb of the form Tb(t nm)/Mo(18 nm) prepared by sputtering and find that these systems show a maximum in the magnitude of the coercivity as a function of layer thickness.¹⁶ This maximum value is 11 kOe and occurs at a value of t (Tb layer thickness) of 9 nm. Thus both systems show a maximum in coercivity at approximately the same size scale, 9 nm layer thickness for Tb multilayers as compared to 7 nm particle diameter for Tb particles. Also the nanoscale particles show a larger maximum coercivity than the multilayers.

We attribute the larger coercivity in the particles to the fact that the particles have a more confined geometry. This more confined geometry can contribute to a larger coercivity

in two ways. Particles will have more surface area per unit volume than multilayers whose layer thickness is the same as the particle diameter. This interface will contribute an anisotropy^{1-3,17} and the total interfacial anisotropy present will be larger in particles than multilayers. Single magnetic domain reversal could also be important here and we are doing more detailed magnetic measurements to determine how each of these effects contribute to the large coercivity in these particles.

In summary, we have prepared a series of nanoscale particle samples of Tb and find that the finite size and large amount of interfacial area strongly modify the properties of these strong anisotropy magnetic systems.

Effect of preparation technique on the structural and magnetic properties of granular Fe-SiO₂ (abstract)

J. A. Christodoulides, N. B. Shevchenko, A. S. Murthy, and G. C. Hadjipanayis
Department of Physics and Astronomy, University of Delaware, Newark, Delaware 19716

Previous studies have shown that large coercivities, exceeding 2 kOe,¹ can be obtained in Fe-based ceramic granular films. The coercivities were also found to be sensitive to the type of matrix material used, being higher in the SiO₂ matrix.² In this study the hysteresis behavior of Fe_x(SiO₂)_{1-x} granular films was studied as a function of the preparation technique. The films were prepared by dc magnetron sputtering over the composition range of $x_v=0.1-0.9$ volume fraction of Fe. Tandem deposition both with and without titanium sublimation, and deposition from a composite target were used in preparing the films, which resulted in different oxygen environments. Coercivity measurements were found to be strongly composition dependent, with maximum values up to 700 Oe at $x_v \approx 0.5$ of Fe, for all sets of samples. Typical granular structure was observed, with grain size in the range of 5–20 nm, with the smaller size obtained from composite targets. X-ray diffraction and selected area diffraction showed a structure of α -Fe (bcc). Thermomagnetic curves showed a peak which can be associated with the onset of superparamagnetism. By varying the deposition method and the oxygen environment, we were able to switch from a relatively magnetically hard sample ($H_c \sim 500$ Oe) to a soft sample ($H_c \sim 20$ Oe). Mossbauer data are being analyzed to determine the presence of any oxides, their magnetic state and their effect on hysteresis. © 1996 American Institute of Physics. [S0021-8979(96)80708-8]

For a complete experimental and theoretical explanation of the magnetic processes in an interacting collection of submicron magnetic particles, a fundamental understanding of the magnetic properties of individual single-domain particles must first be achieved. We have prepared elongated Ni columns ranging in diameter from 0.15 to 1.0 μm by electroplating into specially prepared Al_2O_3 and glass channelled pore membranes. We have also prepared controlled arrays of Ni columns using *e*-beam lithography, subsequently electroplating into the written patterns. Using transmission electron microscopy, we have characterized the shape, size, morphology, and crystal structure of the columns. Magnetic force microscopy has been used to determine the switching field H_s versus the applied field angle of the columns. Although the switching field data can be fit to the functional form for nucleation by curling in an infinite cylinder, the observed weak dependence of H_s on column diameter is inconsistent with that expected for curling, particularly for columns of diameter $>0.3 \mu\text{m}$. © 1996 American Institute of Physics. [S0021-8979(96)40408-4]

I. INTRODUCTION

The magnetization state of a collection of magnetic particles is generally a complicated function of the applied field history and is a problem still lacking a complete theoretical description. The complexity is due mostly to the long range magnetostatic interactions between every pair of particles. Before a fundamental theory for the magnetization reversal of an interacting collection of particles can be formulated, one must first understand the reversal properties of the individual constituents, single-domain particles.

Our approach to this problem is to gather experimental data for the behavior of model single-domain particles specifically prepared for this purpose. Over the past few years, studies of the switching field versus applied field angle have been made on single-domain rectangular permalloy platelets,¹ barium-ferrite platelets,² $\gamma\text{-Fe}_2\text{O}_3$ particles,³ Fe particles,⁴ rectangular Ni platelets,⁵ and long Ni cylinders.⁶ In this article, we describe the preparation, characterization, and magnetic measurements of single-domain elongated Ni columns, and a method used to prepare controlled assemblies of Ni columns in designed configurations.

II. SAMPLE PREPARATION

The method we have used to prepare samples consists of electroplating Ni into channel pore membranes prepared by three different techniques:

A. Anodized aluminum

One type of porous membrane which we have filled by electroplating are Al_2O_3 filters commercially available from Whatman Inc.⁷ Details of the set up and the plating condi-

tions used have been previously reported.⁶ The standard Whatman Al_2O_3 filters have diameters ranging from ~ 0.25 – $0.45 \mu\text{m}$ and we can vary the length of the columns prepared by changing the duration or the current density used in the plating process. We have also utilized a series of custom made filters for which the anodization conditions have been adjusted to produce pores with smaller hole sizes.

B. Nanochannel glass arrays

A second type of porous membranes are nanochannel glass arrays developed by Tonucci *et al.*,⁸ with pore diameters of 1 μm . Nanochannel glass membranes contain highly uniform parallel pores or channels in large arrays. Samples are prepared by polishing a channel glass wafer to a thickness appropriate for the desired column length. The wafer is then etched with a weak acetic acid solution exposing the channels in the array. The channel glass wafer is then sealed over a hole in a glass cover slip in preparation for electrodeposition. Details of the plating conditions were similar to that used for the anodized aluminum samples discussed above.

^{a)}Currently at Read-Rite Corp.

FIG. 2. Dark field TEM image of a particle written by *e*-beam lithography. The scale bar is 0.2 μm .

C. Electron-beam lithography

A third method for preparing columnar pores utilizes electron-beam lithography as reported by Chou *et al.*⁹ The details of our lithography will be included in Ref. 10. In brief, a thin gold layer is evaporated onto a semiconducting or insulating substrate in a pattern that consists of a beam-writing pad and two electrically connected probe contact pads. We then spin-coat a single, high molecular weight polymethyl methacrylate (950k PMMA) resist layer. The resist is then patterned using a Phillips EM-430 scanning transmission electron microscope (STEM) with an acceleration voltage of 250 kV. Following the lithographic exposure, the exposed patterns are developed in a 3:7 cellulose-methanol mixture. Electrodeposition at constant current is then carried out using a nickel sulfamate electrolyte. Using this technique, we have prepared columns ranging from 0.02 to 0.2 μm in diameter, and exceeding 1 μm in length.

III. SAMPLE CHARACTERIZATION

To determine the size, shape, morphology, and crystal structure of the Ni columns, we first remove the surrounding membrane. The Al_2O_3 filters and nanochannel glass membranes are removed by etching in 1 M NaOH. The PMMA is removed by an oxygen plasma etch. The columns can then be observed directly in a SEM or placed in water, ultrasonicated, and evaporated onto a transmission electron microscopic (TEM) grid. Figure 1 shows a bright field image of a

FIG. 3. SEM micrograph of an array of columns written by *e*-beam lithography after removal of the PMMA layer. Column height is $>1 \mu\text{m}$, $d=0.1 \mu\text{m}$, and the spacing between columns $\sim 1 \mu\text{m}$.

FIG. 4. Switching field vs angle between external field and the long axis, $H_s(\theta)$ of column C, and a pair of similar columns aligned end-to-end ($d=1 \mu\text{m}$, and $L=44 \mu\text{m}$), and for column β ($d=.15 \mu\text{m}$, $L=1.65 \mu\text{m}$). The solid and dashed curves correspond to $H_s(\theta)$ for nucleation by curling in an infinite cylinder. For Ni, $R_0=\sqrt{A/M_s}$ is 206 Å, where A is the exchange constant, and M_s is the saturation magnetization.

column previously designated as α ,⁶ prepared using an Al_2O_3 filter. This column has a diameter $d=0.27 \mu\text{m}$, length $L=17 \mu\text{m}$, and an aspect ratio of 63:1.

Figure 2 is a dark field image of a particle written by *e*-beam lithography. As can be seen in this image, the crystal structure is polycrystalline with a decrease in the grain size as the plating progresses. We intend to improve the crystallinity by varying and optimizing the plating parameters. An illustration of an array of columns written by *e*-beam lithography as visualized by SEM after the removal of the PMMA, is shown in Fig. 3.

IV. MEASUREMENT OF MAGNETIC PROPERTIES

Using a magnetic force microscope (MFM)¹¹ with an *in situ* electromagnet, we have measured the switching field versus applied field angle for several different columns. Columns are first located and characterized by TEM on a grid, and then relocated by correlation of various marking features in the MFM. The measurement sequence is as follows. A reverse field of 1650 Oe is pulsed in a direction making an angle θ with the long axis of the column for 1 s. This field is verified to be sufficient to reverse saturate the column's magnetization. A forward field H , is then applied for 2 s. Before the fields are applied, the MFM tip is backed away to a distance of 12 μm . After the application of the field pulses, the column is then imaged in the **remanent state** to see if the forward field H was sufficient to reverse the direction of magnetization. The lowest H necessary to switch the direction of the magnetization of the column is defined as the switching field H_s for that angle.

The results for an isolated column, prepared with nanochannel glass membranes (designated as C) and for two

FIG. 5. MFM images of column A ($d=0.45 \mu\text{m}$, $L=12.7 \mu\text{m}$) scanned in remanence after applying a field of (a) $H=0$ and (b) $H=475$ Oe. For this particular case, $H_s=480$ Oe.

similar columns aligned end-to-end, each with $d=1 \mu\text{m}$ and $L=44 \mu\text{m}$, and for an isolated column prepared with an Al_2O_3 filter (designated β) are presented in Fig. 4. The solid and dashed curves correspond to the analytical micromagnetic solution of $H_s(\theta)$ for curling¹² in an infinite cylinder where we have adjusted R/R_0 to get a best fit, where R is the cylinder radius and R_0 is the critical radius for curling. Even though we don't expect curling to be valid over the entire range, in Fig. 4 we plot the relationships for comparison. MFM images, such as those in Fig. 5, show that magnetic charge is concentrated only at the ends of the columns, with negative charge at one end and positive at the other, with the polarity (of the magnetization) dependent on whether the previously applied field $H > H_s$. At remanence, a multi-domain state has never been observed, even if the previously applied field was near H_s (see Fig. 5). It is surprising that even the columns with $d=1 \mu\text{m}$ are single-domain which may be due to the large aspect ratio which should help to stabilize the single-domain state. The angular dependence for column C is similar to that of columns 1,2 ($d=0.3 \mu\text{m}$, $L=5.5 \mu\text{m}$), A,B ($d=0.45 \mu\text{m}$, $L=12.7 \mu\text{m}$), and α ($d=0.27 \mu\text{m}$, $L=17 \mu\text{m}$) given in Fig. 2 of Ref. 6. The angular dependence for column β ($d=0.15 \mu\text{m}$, $L=1.65 \mu\text{m}$) is different in that H_s increases slightly as θ approaches 0° . The switching field at zero degrees $H_s(\theta=0^\circ)$ versus column radius R is plotted in Fig. 6. The solid line is the solution for the nucleation field via curling in an infinite Ni cylinder. Column β has a zero angle switching field of 276 Oe, a value close to the theoretical curve.

V. CONCLUSION

We have prepared columns by electroplating into porous membranes ranging in diameter from 0.15 to $1.0 \mu\text{m}$ and have measured the switching field versus applied field angle. We have also demonstrated the capability to prepare arrays of columns with diameters as small as $0.02 \mu\text{m}$ using e -beam lithography. In general, the observed angular dependence of the switching field (Fig. 4) agrees with the functional form

$H_s(\theta=0^\circ)$ vs. radius (μm)

FIG. 6. Switching field when the external field is aligned with the column long axis vs column radius. Solid line is the solution given for nucleation by curling in an infinite cylinder.

corresponding to curling in an infinite cylinder, although at the expense of reassigning the R/R_0 value to get a best fit. For Fig. 4 that adjustment is from 24.3 to 6.5 for column C and from 3.64 to 4.2 for column β . For $d > 0.3 \mu\text{m}$, the dependence of H_s on diameter is weak which is not consistent with curling and may indicate another mode for initiating reversal such as nucleation at the particle ends.

Magnetic domain percolation in granular Co-Ag

A. Gavrin^{a)} and M. H. Kelley

National Institute of Standards and Technology, Gaithersburg, Maryland 20899

J. Q. Xiao^{b)} and C. L. Chien

Department of Physics and Astronomy, The Johns Hopkins University, Baltimore, Maryland 21218

The most dramatic changes in the properties of granular metals occur near the percolation threshold x_c , which generally occurs at a volume fraction of approximately 0.50. There has been much speculation concerning the evolution of magnetic domains at x_c , however, no direct observations have been produced. Using scanning electron microscopy with polarization analysis, we investigate the formation of domains in a series of granular Co-Ag samples. We find x_c to lie in the range [0.50, 0.55], and we report on the size and morphology of the observed domains. Below x_c , a domain pattern appears which may be due either to interparticle correlations or to residual Co in the silver matrix; we have previously discussed the ramifications of this observation on an understanding of GMR. In this paper, we place limits on the latter of these two models. Above x_c , the domains resemble "stripe domains" which have been observed in amorphous materials. This observation suggests the presence of anisotropy perpendicular to the film plane. © 1996 American Institute of Physics. [S0021-8979(96)04908-9]

Granular ferromagnets are nanocomposite materials with one ferromagnetic and at least one nonmagnetic component. The ferromagnet may be either a pure metal or an alloy; the remaining material or materials may vary widely, so long as they are immiscible with the ferromagnet. In this paper, we will consider samples in which the ferromagnetic component is pure cobalt, and the nonmagnetic component is silver. Because the components (often called phases) are largely segregated from one another, we give the composition of the samples in terms of the volume fractions of the phases. Thus, we denote our samples $\text{Co}_x\text{Ag}_{1-x}$: a sample with $x=0.40$ contains 40% cobalt by volume, with the balance silver. We selected the cobalt-silver system because the mutual solubility of this pair is minimal, and because of the great recent interest in the magnetoresistance of this system.¹ However, we must state at the outset that the microstructure of our $\text{Co}_x\text{Ag}_{1-x}$ samples may be more complex than the simple picture of granular materials presented here. In particular, there is evidence that the two components are not simply segregated: the samples may have a Co-Ag alloy phase in addition to pure cobalt and pure silver.

Granular ferromagnets have been investigated since the early 1970's, and continue to provide important fundamental results and potential applications.² Many of these are associated with the microstructural transition (often described as a percolation transition) which occurs at a critical volume fraction near to 50%, i.e., $x_c=0.50$. For reasons that we outline below, granular ferromagnets are not expected to have a macroscopic domain structure below x_c , whereas above x_c such a domain structure will develop. There is little doubt that this occurs, and the formation of a domain structure above x_c is an integral part of our understanding of these materials. However, the development of the domain structure

has not, to our knowledge, ever been investigated directly. This paper provides a first investigation of this kind.

The microstructure of a granular ferromagnet affects its magnetic properties primarily through the suppression of domain walls at low volume fractions. Below x_c , the ferromagnetic phase exists in the form of isolated, roughly spherical particles a few nanometers in size. Particles of this size behave as single magnetic domains, thus, we may understand the magnetic properties of the material by considering an ensemble of such particles, possibly including some interparticle interactions. A number of phenomena of theoretical and practical importance have been understood in this way, including superparamagnetism, enhanced coercivity, and giant magnetoresistance (GMR).³ In each case, a crucial feature is the lack of domain walls when the ferromagnetic particles are small and isolated from one another. The magnetic response of such a material does not include a component due to the motion of domain walls—the dominant component in most magnetic materials. Above the critical volume fraction the ferromagnetic material "percolates" through the material; thus, magnetic domains may form, and the response of the material to an external field will include domain wall motion.

We have used high-resolution scanning electron microscopy with polarization analysis (SEMPA) to image the magnetic domain structure of our $\text{Co}_x\text{Ag}_{1-x}$ samples over a range of volume fractions including x_c . We have previously reported the (somewhat surprising) existence of a domain structure below x_c , and we have discussed possible origins of these domains.⁴ In particular, we have considered domain formation due to interparticle interactions and due to residual cobalt in the silver matrix. In this paper, we extend the range of our investigation to compositions well beyond the critical volume fraction. Between $x=0.50$ and $x=0.55$ the domain structure changes dramatically, suggesting the onset of percolation. Thus, we identify the critical volume fraction $0.50 \leq x_c \leq 0.55$.

We produced the materials described herein by dc mag-

neutron sputtering from composite targets, the details may be found elsewhere.⁵ The samples cover the composition range $0.35 \leq x \leq 0.65$, and have been vacuum annealed at temperatures up to 600 °C. For comparison, we have also produced a pure cobalt film under identical conditions. The annealing temperatures are known to ± 25 °C and the sample compositions are known to ± 0.005 .⁶ Annealing was performed under vacuum, at pressure $p \leq 7.0 \times 10^{-5}$ Pa.

The magnetic images were acquired by using SEMPA. The principles of this technique have been described previously.⁷ In brief, the SEMPA microscope independently records two orthogonal components of the magnetization in the plane of the sample. Subsequently, we employ digital image processing to determine the direction and magnitude of the in-plane magnetization vector. Near the surface, the in-plane component accounts for nearly all of the magnetization, because moments that are perpendicular to the surface are energetically costly. We recorded all of the images at room temperature.

The magnetic information recorded by the SEMPA system is carried by low-energy secondary electrons (≤ 10 eV). The mean-free path of these electrons is exceedingly short, only a few nanometers. Thus, the domain structures recorded by the SEMPA are those present in the first few monolayers at the sample surface. This has two important ramifications: the sample must be free of surface contamination, and the domain pattern in the bulk of the sample must be inferred from the surface domains and micromagnetic principles. We clean the sample surface under UHV conditions using ion bombardment with 1.15 keV Ar⁺ ions. A discussion of the extension from surface to bulk will be included later in this paper.

Many aspects of our results are evident in Figs. 1(a)–1(d), in which we present the domains in four Co_xAg_{1-x} samples. These images were recorded at moderate magnification (10 k \times) in order to illustrate the typical domain sizes and morphologies at several compositions. In these images, we display the direction of the magnetization vector for four samples: $x = [0.40, 0.50, 0.55, 0.65]$. All of the samples are as-deposited. The “grey wheel” in the upper left corner of Fig. 1(a) shows the correspondence between angle and grey level. Pure black and pure white correspond to magnetization in the + x direction, 75% grey to + y , etc. The artificial discontinuity between black and white is unfortunate, but does not significantly affect the issues we wish to discuss here.

The differences between Figs. 1(a), 1(b) and Figs. 1(c), 1(d) are striking. The former show domains that are typically 300–600 nm in extent, and are fairly isotropic. In contrast, the latter show domains that are highly anisotropic, extending for tens of microns along one direction and approximately 1 μ m in the orthogonal direction. Furthermore, the domains in 1(a) and 1(b) have previously been shown to lack any substructure down to length scale of about 20 nm,⁴ whereas Fig. 2(b) reveals a complex substructure to the domains shown in Fig. 1(d).

In Fig. 2, we present low (2 k \times) and high (100 k \times) magnification images of a sample with $x = 0.65$ —the same as that imaged in Fig. 1(d). The low magnification image, Fig. 2(b), illustrates the full extent of the domain pattern over

FIG. 1. Domain images of Co_xAg_{1-x} at a magnification of 10 k \times . The compositions are (a) $x = 0.45$, (b) $x = 0.50$, (c) $x = 0.55$, and (d) $x = 0.65$. The greywheel in (a) illustrates the correspondence between direction and grey value. In each of these images, the physical size of one pixel is 89.3 nm. The micron marker in (d) applies to each image.

long distances; the high magnification image, Fig. 2(b), shows the complex substructure of the domains. Figure 2(c) is a vector map derived from the data shown in Fig. 2(b). This representation reveals the presence of several surface magnetic singularities. Structures such as these are indicative of magnetization perpendicular to the sample plane, and were also observed at lower volume fractions.⁴

We must consider what bulk domain-pattern could give rise to these surface domains. The alternating dark and light bands observed in Fig. 2(a) represent domains that are head-to-head and tail-to-tail. We illustrate this situation schematically in Fig. 3(a). Such a situation is extremely unlikely to persist in the bulk, because a discontinuity in the perpendicular component of M across an interface is equivalent to a sheet of magnetic charge: a very high-energy situation. In Fig. 3(b), we illustrate the possibility that the observed domains are closure domains at the surface of a bulk domain

FIG. 2. SEMPA images of Co_{0.65}Ag_{0.35}. (a) Magnification of 2 k \times , the physical size of each pixel is 112 nm. (b) Magnification of 100 k \times , physical size of each pixel is 8.93 nm. (c) Vector map representation of the domains shown in (b).

pattern perpendicular to the film plane. This model is supported by hysteresis measurements that we present in a separate paper.⁸ We note the similarity between these domains and "stripe domains" which have been observed in amorphous metal films,⁹ and wires,¹⁰ and which have also been attributed to closure domains.

A more vexing question is the degree of segregation between the cobalt and silver; previous results provide a mixed picture. The magnetic properties of the samples suggest that there is substantial segregation. Samples with $x \leq 0.30$ show superparamagnetic relaxation with blocking temperatures below room temperature.¹¹ Furthermore, it is widely accepted that giant magnetoresistance can only occur in the presence of short range magnetic disorder. In Co-Ag this disorder is usually assumed to result from the random orientations of the moments of individual magnetic particles.³ In opposition, our observation of magnetic domains at low x can be readily understood if enough cobalt remains dissolved in the silver to maintain ferromagnetism of the alloy. There are also preliminary microanalytic results indicating that the samples may contain pure silver particles in a Co-Ag alloy matrix.¹²

We have previously demonstrated that some fraction of the cobalt in our samples does not participate in the GMR. In particular, we have considered the possibility that some of the cobalt remains dissolved in the alloy matrix while the remainder resides in single-domain particles that are responsible for the GMR. In this case, the matrix material remains ferromagnetic and supports the domains that we observe at $x \leq 0.50$. In Ref. 4 we argued that this model is subject to two constraints: the concentration of cobalt in the matrix (α) must be high enough to support ferromagnetism at room temperature, and the volume fraction of the matrix (y) must be great enough for the matrix to percolate. We considered $\alpha \geq 0.30$ and $y \geq 0.27$ or $y \geq 0.55$. Using these conditions, we discussed the sample with $x = 0.35$ and calculated the maxi-

mum volume fraction of cobalt in the small particle phase to be $x_{\text{max}} = 0.22 - 0.29 \pm 0.01$ (depending on the requirement for percolation of the matrix). In essence, this argument sets a lower limit on the degree of segregation of the sample.

If we assume that the change in the domain structure above $x = 0.55$ represents percolation of the pure cobalt phase, then the present result sets an upper limit on segregation. Taking the matrix phase to contain the same minimum cobalt content (30 at. %), the range of possible volume fractions for pure cobalt becomes $x_{\text{segregated}} = 0.40 - 0.55 \pm 0.01$. That is, minimum segregation corresponds to a percolation threshold of $x_c = 0.40$ and maximum segregation gives $x_c = 0.55$. Taking percolation to occur at 0.45, and applying the same degree of segregation to the example above yields $x_{\text{max}} = 0.20 \pm 0.01$, near the lower given above. Thus, only $20/35 \approx 57\%$ of the cobalt participates in the GMR.

This result in no way rules out the other model suggested in Ref. 4. If the domains observed at $x \leq 0.50$ result from correlations among single-particle moments in a well-segregated sample, then the transition observed here may be simply understood. The small domains at low x are the result of dipole-dipole and exchange interactions through a non-magnetic matrix phase; the large domains occur above percolation as a result of direct exchange.

Granular Co-Ag materials with low Co contents exhibit giant magnetoresistance and single-domain magnetic properties. In this paper, we discuss unusual hysteresis behavior that we have observed in Co-rich samples, where the magnetization is approximately linear with the applied field up to saturation, and the coercivity and remnant magnetization are both nearly zero. We attribute this unusual behavior to a perpendicular anisotropy that depends on the nanostructure in the phase-segregated materials. These results are corroborated by magnetic domain imaging using scanning electron microscopy with polarization analysis. © 1996 American Institute of Physics. [S0021-8979(96)01808-7]

Recently, granular metallic solids have been extensively studied due to the discovery of giant magnetoresistance (GMR),^{1,2} enhanced coercivity (H_c),³ extraordinary Hall effect,⁴ giant magnetothermal properties,⁵ and other enhanced properties. Granular metallic solids can be conveniently produced by cosputtering of two immiscible metals.⁶ Using low substrate temperatures, the as-prepared samples may be metastable crystalline alloys. Post-deposition annealing or the use of elevated substrate temperatures result in the formation of granular solids; the size of the ultrafine particles can be adjusted by varying the substrate or annealing temperature.

Numerous studies of granular solids have established that isolated granules are found in samples with low volume fractions. For samples with volume fraction (x) above the percolation volume fraction (x_p), the granules form a continuous network. For a wide variety of magnetic granular solids, the values of x_p have been near 0.5.³ High coercivity and GMR are realized for samples with $x < x_p$. Above x_p , the coercivity reverts to small values and there is no GMR. Consequently, the magnetic properties of granular solids with $x > x_p$ are usually considered uninteresting.

Very recently, we have imaged the domain structures in the demagnetized state of granular $\text{Co}_x\text{Ag}_{1-x}$ by using scanning electron microscopy with polarization analysis (SEMPA).^{7,8} The results suggest that the magnetization may have an out-of-plane component, a prospect generally not expected in thin magnetic films. In this work we report the observation of perpendicular anisotropy in granular magnetic materials. This perpendicular anisotropy is most pronounced near the percolation threshold ($x \approx 0.5$), and occurs only in phase separated magnetic systems. The phenomenon is not material specific, and has been observed in a number of granular magnetic systems. In this paper we confine ourselves to the results in $\text{Co}_x\text{Ag}_{1-x}$, and other results will be discussed elsewhere.

Thin-film samples, several μm thick, of $\text{Co}_x\text{Ag}_{1-x}$ with Co volume fraction $0.35 \leq x \leq 0.75$, were fabricated using dc

magnetron sputtering onto room-temperature Si(100) substrates.³ Some of the samples have been annealed in a vacuum at temperatures of $T_A = 300$ and 600°C . We have analyzed the sample structures using x-ray diffraction; the magnetic properties have been measured using a vibrating sample magnetometer (VSM).

Figure 1 shows x-ray diffraction results of the as-prepared $\text{Co}_x\text{Ag}_{1-x}$ samples with $x = 0.55, 0.65$, and 0.75 . Despite larger contents of Co, the diffraction peaks due to Ag [Ag(111) and Ag(200)] are more prominent than those of Co [Co(100) and Co(002)] because of the larger scattering factor of Ag. The Co(002) peak is not resolvable because it is practically at the same position as that of Ag(200). The appearance of both Co and Ag peaks in Fig. 1 shows that phase separation has occurred in the sample with $x = 0.75$, although less obvious in the samples with $x = 0.55$ and 0.65 , because the Co(100) peak is barely observable. Some Co-Ag alloys may also be present. After annealing at $T_A = 300$ and 600°C , we clearly observe diffraction patterns of Co and Ag with narrower lines due to larger grain sizes.

In Fig. 2 we show the magnetic hysteresis loops at room temperature for the as-prepared ($T_A = 27^\circ\text{C}$) and the annealed samples ($T_A = 300$ and 600°C) of $\text{Co}_{0.65}\text{Ag}_{0.35}$. In

FIG. 2. Magnetic hysteresis loops with an in-plane (\parallel , open symbols) and out-of-plane (\perp , solid symbols) external fields of $\text{Co}_{0.65}\text{Ag}_{0.35}$ annealed at (a) 27 °C, (b) 300 °C, and (c) 600 °C.

each case, solid and open symbols denote results of measurements with the external field applied parallel and perpendicular to the film plane, respectively. Beginning with the results shown in Fig. 2(a) for parallel field (H_{\parallel}), we note several unexpected features. A much larger than expected saturation field ($H_{s\parallel}$), of about 3 kOe, is required to align the magnetization in the film plane. The hysteresis loop with parallel field is linear in H_{\parallel} , exhibiting practically zero remanence and coercivity. The hysteresis should exhibit a large remanence and a coercivity of a few tens of Oe. The results obtained under a perpendicular field (H_{\perp}) are similar, except that the saturation field ($H_{s\perp}$) is even larger, about 10 kOe. The magnetization is also linear in H_{\perp} . These features, totally different from those of homogeneous and polycrystalline Co films, suggest the existence of a strong perpendicular anisotropy, in addition to the usual shape anisotropy. In Table I, we list the values of $H_{s\parallel}$, $H_{s\perp}$, and the saturation magne-

TABLE I. Saturation fields in parallel field ($H_{s\parallel}$) and perpendicular field ($H_{s\perp}$), saturation magnetization ($4\pi M_s$), anisotropy constant (K) of granular $\text{Co}_x\text{Ag}_{1-x}$ with Co volume fraction x , and θ is the angle between the anisotropy axis and the film normal.

x	$H_{s\parallel}$ (Oe)	$H_{s\perp}$ (Oe)	$4\pi M_s$ (G)	K (10^6 ergs/cm 3)	θ (degree)
0.35	2630	4130	4273	0.42	0
0.40	3400	5670	5579	0.77	5
0.45	3670	6530	6672	0.94	0
0.50	3750	6250	6208	0.94	6
0.55	3600	7700	8004	1.05	0
0.65	3250	10200	9550	1.48	24
0.75	2600	12400	11008	1.75	36

tization ($4\pi M_s$) for various samples of $\text{Co}_x\text{Ag}_{1-x}$ with $0.35 \leq x \leq 0.75$. Here the value of M_s is in emu/cm 3 , that is, per volume of the $\text{Co}_x\text{Ag}_{1-x}$ sample.

To facilitate further discussion of this unexpected anisotropy, we first review the consequence of an additional magnetic anisotropy of energy K with an angle θ with respect to the film normal.⁹ For the moment, we will neglect the magnetocrystalline energy for simplicity. When the magnetization is aligned in the film plane at $H = H_{s\parallel}$, we have

$$-\frac{1}{2} M_s H_{s\parallel} + K \cos^2 \theta = 0 \quad (1)$$

or

$$H_{\parallel} = \frac{2K \cos^2 \theta}{M_s}. \quad (2)$$

Similarly, when the magnetization is aligned perpendicular to the film at $H = H_{s\perp}$, we have

$$2\pi M_s^2 - \frac{1}{2} M_s H_{s\perp} + K \sin^2 \theta = 0 \quad (3)$$

or

$$H_{s\perp} = 4\pi M_s + \frac{2K \sin^2 \theta}{M_s}, \quad (4)$$

where the first term in Eq. (3) is the contribution of the demagnetization field. It may be noted that

$$H_{s\parallel} + H_{s\perp} = 4\pi M_s + \frac{2K}{M_s}. \quad (5)$$

According to this simple analysis, from the experimentally measured values of $H_{s\parallel}$, $H_{s\perp}$, and M_s , one can determine the value of K using Eq. (5). The angle θ can be consistently determined using Eq. (2) or Eq. (4). We summarize these results in Table I. First, the unexpected hysteresis loops shown in Fig. 2, and the large values of $H_{s\parallel}$ and $H_{s\perp}$ can be well accounted for by using this simple model that includes an additional *uniaxial* anisotropy. This anisotropy is essentially *perpendicular* ($\theta \approx 0$) for granular samples with low volume fractions as well as those near the percolation threshold (e.g., $x \approx 0.5$). Only above the percolation threshold, does the angle θ increase with increasing Co concentration. We also note that the largely perpendicular anisotropy is not strong enough to overcome the demagnetization field: the magnetization axis does not spontaneously point in the normal direction of the film plane.

The deduced values of K , as listed in Table I, indicate that the perpendicular anisotropy is related to the volume fraction and hence to interparticle interactions. Its magnitude is minimum for samples with low values of x , becomes larger at larger x and surely becomes in-plane ($\theta = 90^\circ$) at $x = 1$. Similar results have also been observed in other granular systems. We would also like to emphasize that the magnetic anisotropy with constant K here is different, in both magnitude and characteristics, from the magnetic surface anisotropy constant with K_s observed in certain magnetic multilayers. The value of $K \approx 1 \times 10^6$ ergs/cm 3 for granular Co-Ag is much smaller than $K_s = 3 - 7 \times 10^6$ ergs/cm 3 ob-

FIG. 3. Proposed domain structure of granular solids with perpendicular anisotropy, where "D" and "S" represent the "drain" and "source" points, respectively, observed in surface domain structure.

served in Co/Pd multilayers. Furthermore, in Co/Pd multilayers, the easy magnetic axis is perpendicular to the plane.¹⁰

As shown in Fig. 2(b), after annealing at $T_A=300^\circ\text{C}$, the results do not change appreciably. However, for the sample annealed at $T_A=600^\circ\text{C}$, the unusual hysteresis loop has reverted to the anticipated and normal shape, as shown in Fig. 2(c), having a square loop for the H_{\parallel} measurement, and the H_{\perp} loop extends to $4\pi M_s$. Furthermore, both loops exhibit a coercivity and a sizable remanence as homogeneous Co films would. Evidently, the subtle nanostructure that causes the perpendicular anisotropy has been altered by the $T_A=600^\circ\text{C}$ annealing.

The highly unusual and certainly unexpected results from the magnetic measurements corroborate the domain structures recently imaged by SEMPA.^{7,8} We would like to point out that the SEMPA technique is highly surface sensitive, whereas hysteresis loops are bulk magnetization measurements. At the sample surface, SEMPA measurements show stripe domains with alternating "sources" and "drains." Together with the results of the magnetic measurements, a model for the domains within the thickness of the sample is shown in Fig. 3. While most of the domains within the thin films are perpendicular to the film plane, the surface domain structures consist of stripes with alternating source and drain, which are indicated by the letters "S" and "D," respectively.

The key question is the source of this elusive anisotropy, which is largely perpendicular to the film plane, as shown in Fig. 3. All the results indicate that the perpendicular anisotropy is related to the nanostructure and not the materials. It may be emphasized again that the unexpected hysteresis

loops occur only in phase-separated materials. In metastable alloys with no phase separation, using low substrate temperatures for example, one does not observe the unusual hysteresis loops. This rules out any deposition-related mechanisms. Since phase separation is a prerequisite, the nanostructure must contain unusual arrangements of the Co phase. While direct experimental verifications are underway, we suggest two possibilities. The Co phase may have a preferential crystalline orientation; then in the simple model outlined above, the anisotropy constant K is in fact the magnetocrystalline anisotropy constant, perhaps modified to reflect the far from ideal orientation. The value of $K \approx 10^6$ ergs/cm³ is within an order of magnitude of the magnetocrystalline anisotropy constant for bulk Co.⁹ The other possibility involves preferential arrangement of the Co particles in the direction perpendicular to the film plane. These scenarios can in principle be resolved using high-resolution characterizations.

In summary, we have found unusual hysteresis loops in magnetic granular solids. The hysteresis loops are characterized by large saturation fields and a linear dependence of the applied field with zero remanence and coercivity. These unusual results are due to the perpendicular anisotropy present in the phase-separated materials with certain nanostructure.

Self-stabilized magnetic colloids: Ultrafine Co particles in polymers

Diandra L. Leslie-Pelecky,^{a)} X. Q. Zhang,^{b)} and Reuben D. Rieke^{b)}
Center for Materials Research & Analysis, University of Nebraska, Lincoln, Nebraska 68588

Self-stabilized magnetic colloids consist of magnetic particles dispersed in an appropriate matrix. Fixing the particles in a stabilizing matrix has the advantage of preventing particle agglomeration, increasing resistance to oxidation, and allowing control over the interparticle spacing and particle size. We describe the chemical synthesis of cobalt nanoparticles in a polystyrene/triphenylphosphine polymer matrix. Depending on the synthesis parameters, magnetic properties of the as-synthesized nanocomposites range from superparamagnetic to ferromagnetic with coercivities on the order of 130 Oe. Solvent choice and polymer crosslinking significantly affect the magnetic properties. Annealing in vacuum produces coercivities of up to 600 Oe and remanence ratios of up to 0.4. Measurement of the isothermal remanence magnetization and dc demagnetization indicate the presence of both magnetizing and demagnetizing interactions, in contrast to particles synthesized without the polymer, which show no evidence for magnetizing interactions. The zero-field-cooled temperature-dependent magnetization displays a cusp, while the field-cooled magnetization increases monotonically below the cusp temperature. Glassy behavior is observed for temperatures below the cusp, although the mechanism producing this behavior is not yet understood. © 1996 American Institute of Physics. [S0021-8979(96)01908-3]

Nanoscale particles have unique electrical, chemical, structural, and magnetic properties, with potential applications in information storage, color imaging, catalysis, bioprocessing, magnetic refrigeration, and ferrofluids.¹ Fabrication techniques for the production of ultrafine particles include: gas condensation,² inverse micelle synthesis,³ arc techniques,⁴ sputtering,^{5,6} self-assembled phospholipids,⁷ chemical reduction,⁸⁻¹⁰ and microemulsion synthesis¹¹ among others. Studies of these systems are often hampered by two problems. First, the large ratio of surface-to-bulk atoms results in high reactivity. While desirable for catalysis, reaction with oxygen can adversely affect magnetic properties. Controlled passivation can deactivate the particle surface; however, this may form additional magnetic phases that complicate analysis. The second problem is the spontaneous production of macroscopic-sized agglomerates that lack the unique properties of nanoscale particles.

The fabrication of highly reactive particles by the reduction of metal halides was pioneered by Rieke and collaborators.⁹ In this technique, a metal salt is reduced using a hydrocarbon or ethereal solvent in the presence of lithium and naphthalene. We have extended this technique to fabricate cobalt particles in a polymer matrix, which decreases agglomeration and improves oxidation resistance.

Self-stabilized colloids have been fabricated using other techniques, including ion exchange^{1,12} and sputtering;⁶ however, in most cases the particle size is small and cannot be conveniently varied. These systems tend to be superparamagnetic unless the metal volume concentration is above the percolation point. On the other end of the size scale, macroscopic composites of 10–100 μm transition metal¹³ and ferrite¹⁴ powders in polymers have been fabricated to study modifications of electrical and magnetic properties.

We have synthesized Co nanocomposites using a poly-

styrene backbone and triphenylphosphine sidechains. Samples have been synthesized using both a commercially available crosslinked polymer and a linear polymer. Different solvents were chosen to assist in the synthesis: solvent choice has been shown to affect particle size during standard syntheses⁹ (i.e., without the polymeric matrix). The cobalt loading was determined to be 70% through chemical assaying. X-ray diffraction of the as-synthesized samples shows no evidence of crystalline cobalt; however, the volume fraction of the cobalt compared to the polymer is very small.

Samples were sealed in Pyrex tubes under vacuum and annealed at temperatures up to 350 °C for the crosslinked samples and 160 °C for the linear samples. Magnetic measurements were made using an alternating gradient force magnetometer and a SQUID susceptometer. In both cases, powders were loaded into a paraffin-filled polyethylene bag in an argon atmosphere. The samples were sealed into the bags and the paraffin melted to prevent magnetization rotation due to physical rotation of an entire particle. All bagged samples were stored in a vacuum desiccator.

All of the samples were ferromagnetic in their as-synthesized state, except for the linear polymer synthesized with THF, which was superparamagnetic. Table I summarizes the magnetic parameters for each of the different syntheses. The choice of polymer type and solvent produce significant variations in the magnetic properties of the four runs. Solvent selection has been shown to affect particle size in similar syntheses,¹⁵ as has the degree of crosslinking.

FIG. 1. The dependence of the coercivity H_c and the remanence ratio M_r/M_s on annealing time at different temperatures for Run 33 (crosslinked polymer, ether solvent).

Figure 1 shows the dependence of the coercivity H_c and remanence ratio M_r/M_s on annealing time for Run 33 (crosslinked polymer, ether solvent). H_c rises rapidly from 56 to 450–600 Oe after short (<1 h) annealing times. Samples annealed at $T > 300$ °C experience a significant decrease in coercivity after 2 h of annealing. Longer annealing times at lower temperatures result in a slight continued increase in both H_c and M_r/M_s , with values plateauing after about 10 h. Samples annealed at $T < 200$ °C (not shown in Fig. 1) follow the same qualitative behavior as the data shown for annealing at 200 °C, but plateau at lower values. Similar behavior is observed for Run 34 (initially crosslinked polymer, toluene solvent). This run has a higher initial H_c , but annealing produces less of an increase in the coercivity and the remanence ratio. H_c never rises above 225 Oe and M_r/M_s is ≤ 0.2 for all annealing conditions.

The effect of solvent choice on particle size and crystallinity is not well understood. One possibility is that the solvents form protective coatings around the particles, limiting particle size. Our studies of particles synthesized without the polymer matrix suggest that the metal particles are initially crystalline on the scale of 2–5 nm, with amorphous material surrounding the crystallites. Short-time annealing slightly increases the size of the crystallites without allowing significant agglomeration. Transmission electron microscopy and mass calculations of particle syntheses without a matrix indicate that lithium, naphthalene and/or some of the solvent is retained within the particles. Annealing may vaporize trapped organics, allowing crystallite growth.

In the initially linear polymers, annealing was performed at temperatures up to 160 °C (20 °C above the glass transition temperature of the undoped polymer). H_c and M_r/M_s both initially rise with increasing annealing time, then plateau around 2–4 h, regardless of the annealing temperature. Figure 2 shows H_c and M_r/M_s as a function of annealing temperature for samples annealed for 1 h. The toluene-based samples (shown as circles) achieve maximum coercivity and remanence ratio for annealing temperatures of 125–130 °C,

FIG. 2. The dependence of the coercivity H_c and the remanence ratio M_r/M_s on annealing temperature for samples made with initially linear polymer. Samples made with THF are shown as squares and those made with toluene are shown as circles.

while the THF-based samples (shown as squares) display monotonically increasing values of these parameters with increasing annealing temperature.

The isothermal remanent magnetization (IRM) and dc demagnetization (DCD) have been measured to investigate the nature of the magnetic interactions. The IRM is measured from a field demagnetized state in which the initial moment is $< 0.1\%$ M_s . Kelly *et al.*,¹⁶ following Wohlfarth,¹⁷ suggested that deviations from the ideal system of single-domain, noninteracting uniaxial particles will have a nonzero value of ΔM , where ΔM is defined by

$$\Delta M(H) = \frac{M^{\text{DCD}}(H)}{M^{\text{IRM}}(\infty)} - \left(1 - 2 \frac{M^{\text{IRM}}(H)}{M^{\text{IRM}}(\infty)} \right). \quad (1)$$

Positive values of $\Delta M(H)$ are due to stabilizing (ferromagnetic) interactions, while negative values can be attributed to demagnetizing (antiferromagnetic) interactions. Fig-

FIG. 3. (a) The isothermal remanent magnetization $M^{\text{IRM}}(H)$ and the dc demagnetization remanence $M^{\text{DCD}}(H)$. (b) The quantity ΔM , as defined by Eq. (1).

FIG. 4. The zero-field-cooled (ZFC) and field-cooled (FC) magnetization. The magnetization is normalized to the density of the nanocomposite.

Figure 3(a) shows $M^{\text{DCD}}(H)$ and $M^{\text{IRM}}(H)$ (both normalized) for a sample from Run 34 (crosslinked polymer, toluene solvent) annealed at 200 °C for 8 h. Figure 3(b), which shows $\Delta M(H)$, indicates the presence of both magnetizing and demagnetizing interactions. The predominantly demagnetizing interactions seen in Fig. 3(b) are consistent with the remanence ratio of 0.33 for this sample. The presence of both types of interactions in the same sample has been previously observed.^{18,19} Contrary to the nanocomposites, particles without the polymer matrix do not exhibit evidence of any magnetizing interactions. The data shown in Fig. 3 are qualitatively representative of both crosslinked and linear polymer samples, although the ratio of magnetizing to demagnetizing interactions varies with annealing time and solvent choice.

$M(T, H=100 \text{ Oe})$ is shown in Fig. 4 for field-cooled (FC) and zero-field-cooled (ZFC) measurements of an unannealed sample from Run 57 (linear polymer, toluene solvent). The undoped polymer exhibits a diamagnetic plus a Curie-Weiss magnetization with no dependence on the presence of a cooling field. The ZFC magnetization exhibits a cusp at about 5 K, with the temperature of the cusp decreasing as the interactions—measured by the remanence ratio—decrease. The width of the cusp increases in more strongly interacting systems. The FC magnetization follows the ZFC curve until a temperature of about 10 K, at which point the two curves depart and the FC curve continues to rise. As the measuring field increases, the cusp temperature decreases, and the cusp broadens and flattens. Measurements below the cusp temperature show behavior similar to that seen in glassy systems, such as spin glasses and frozen ferrofluids with random anisotropy;²⁰ however, more detailed, systematic measurements are required to determine the nature of the phenomena producing the cusp.

In conclusion, we have demonstrated a synthesis technique for fabricating self-stabilized magnetic colloids consisting of cobalt nanoparticles embedded in a polymer matrix. Variation of solvent type, degree of polymer crosslinking, and annealing parameters can all significantly affect the magnetic properties. Determination of structural properties, which is complicated by the small volume fraction of cobalt to polymer, is necessary to better understand the magnetic properties. Each of the fabricated systems exhibits a cusp in the zero-field-cooled magnetization, and differences between the field-cooled and zero-field-cooled behavior. Data taken below the cusp is indicative of glassy behavior. Much work remains to better understand the properties of this novel system.

A magneto-optical indicator film (MOIF) technique and magnetic force microscopy were used for visualization and direct real-time experimental study of the magnetization processes of magnetic $\text{Co}_{90}\text{Ag}_{10}$ granular films. It is shown that the magnetization reversal of the as-deposited films follows a specific two-step course. The first stage is characterized by gradual spin rotation to large angles up to 90° without domain formation. Further magnetization reversal proceeds by the nucleation and motion of zigzag-shaped domain walls. The dendritic structure of the domain walls was observed using both techniques. Also tracks of magnetic inhomogeneities remaining behind moving zigzag-shaped domain walls was revealed by MOIF. © 1996 American Institute of Physics. [S0021-8979(96)05008-3]

In the last few years nanostructured materials consisting of magnetic and nonmagnetic components have attracted a great deal of attention.^{1,2} It has been discovered that such materials exhibit peculiar properties, in particular giant magneto resistance. These materials are very attractive for use in the next generation of magnetic field sensors and computer disk drive reading elements. As a result, the development of experimental techniques for the investigation of real-time magnetization dynamics and nondestructive characterization of magnetic multilayered and clustered systems is of great interest.³⁻⁶

In this paper we demonstrate the use of a novel magneto-optical indicator film (MOIF) technique for the study of ferromagnetic granular films. The MOIF technique was initially developed for investigation of magnetization processes and quality characterization of high-temperature superconductors,⁷ and has more recently been used to study magnetic multilayers.⁸ We also illustrate the use of magnetic force microscopy (MFM) as a complementary method to MOIF. With MFM one can study magnetic structures smaller than can be resolved via MOIF. Magnetic features as small as 10 nm have been reported using MFM,⁹ but such resolution is sample dependent, and the sample studied here revealed no significant features smaller than about 250 nm.

The Co-Ag granular films were prepared at room temperature by laser sputtering on glass substrates in a vacuum chamber at a pressure of approximately 10^{-4} Pa. A $1.06\text{ }\mu\text{m}$ wavelength pulse laser was used with 10 ns pulses at a rate of 25 s^{-1} . The target was pressed from Co and Ag powders and annealed in a vacuum at 800°C for 4 h. The nominal composition of the 1000-Å-thick films was 90% Co and 10% Ag (atomic fractions). The grain size was shown by scanning electron microscopy to be $\approx 0.2\text{ }\mu\text{m}$.

The MOIF technique^{7,8} places on top of the sample a transparent Bi-substituted iron garnet indicator film with in-plane anisotropy. Polarized light is passed through the indicator film and is reflected by an Al underlayer. The normal

component of the magnetic stray field (B_z) is detected in a polarized microscope by the magneto-optic Faraday effect.

The magnetic force microscopy (MFM) investigations employed a standard commercial microscope utilizing a dual scan technique. In the first pass a cantilever with an integral magnetized tip is tapped along the surface to determine the sample's topography. A second scan is then performed that tracks at a constant height (typically $\approx 75\text{ nm}$) above the surface while vibrating the cantilever. In contrast to the MOIF technique which responds to B_z , the MFM is sensitive to $\partial B_z/\partial z$ or $\partial^2 B_z/\partial z^2$.^{10,11}

A typical granular film magnetization reversal is illustrated in Figs. 1(a)–1(f). Figure 1(a) shows the MOIF image resulting from a saturating in-plane magnetic field of 150 mT

FIG. 1. MOIF patterns demonstrating a two-step magnetization of a ferromagnetic granular $\text{Co}_{90}\text{Ag}_{10}$ film. Direction of magnetic field H and approximate magnetization vectors are indicated. (a) $H=150\text{ mT}$, (b) -2.4 mT , (c) -2.65 mT , (d), (e) -3.05 mT , (f) -3.4 mT . (e) is obtained within 30 s of (d).

FIG. 2. MOIF image of tree-like domain walls.

directed parallel to the lower left edge of the film. The dark thin stripe indicates magnetic flux entering the sample through the edge perpendicular to the external field. The gray tone of the edge parallel to the field indicates that the magnetization is directed along this edge. This image changes only slightly as the applied field is reduced to zero, but when a field in the opposite direction is applied and is slowly increased, the MOIF pattern changes. Figure 1(b) was obtained after the field was brought to -2.4 mT. The edge parallel to the applied field becomes dark, whereas the perpendicular edge is seen to be gray, indicating that the magnetization has rotated to the direction approximately perpendicular to the magnetic field. The magnetization rotation proceeds gradually and somewhat nonuniformly as the magnetic field is increased. A further increase in the applied field causes the nucleation and growth of domains with magnetization parallel to the external field [Figs. 1(c)–1(f)]. The direction of the magnetization in the domains is established by analysis of the stray fields at the sample edges [compare, for example, the tone of the sample edges in Figs. 1(e) and 1(f)], and has been independently verified via vector vibrating sample magnetometer (VSM) measurements.

An important feature of the motion of the nucleated 90° domain walls is their creep. This phenomenon is apparent from a comparison of Figs. 1(d) and 1(e) which are at the same field value, but Fig. 1(e) was obtained within 30 s of Fig. 1(d). Although the applied field is not changed, a considerable displacement of the domain walls is observed. Time dependence of magnetization is often found to follow the form $M = M_0 - S \ln(t/\tau)$. The magnetic viscosity coefficient S has been shown to be related to the irreversible susceptibility, χ_{irr} by $S = kT\chi_{irr}/vM$, where v is the activation volume, roughly the inverse of the pinning site density.¹² Because χ_{irr} is large and we expect a high density of pinning sites at Ag inclusions in the predominantly Co film, significant time-dependent effects are not surprising.

The two-step magnetization process (gradual rotation of the magnetization up to a large angle followed by nucleation

FIG. 3. Domain structures in a Co-Ag granular film, imaged by (a) MOIF, and (b),(c) higher-resolution MFM as indicated.

and growth of domains) is observed when the the external magnetic is applied in any direction in the film plane, although the details may differ. In particular, the critical magnetization angle and the form and size of the domain walls will vary with the field direction, though they are always arranged along the magnetic field direction. VSM measurements have confirmed a uniaxial anisotropy much smaller than the magnetocrystalline anisotropy of pure Co granules, so it is reasonable to suspect that these films are comprised of randomly oriented uniaxial Co clusters coupled by strong exchange interactions.

The large-scale domain walls shown in Fig. 2 have a zigzag form typical for charged walls, but a more fine tree-like structure can also be discerned. A similar structure is studied in Fig. 3, where one section of the film is imaged using both MOIF and MFM, in zero applied field. Figure 3(a) is the MOIF image, with two rectangles indicating the

regions where higher resolution MFM scans were performed [Figs. 3(b) and 3(c)]. It is clear from the first MFM image that the black line has a complicated structure with multiple sections. This can just be discerned in the MOIF image, but the fine cross-tie pattern revealed by the MFM scans is not evident in Fig. 3(a). Figure 3(c) shows that the tip of the sawtooth has a more complicated dendritic structure than is apparent from the MOIF image. Just outside and below this image is a micron-scale pit in the film surface that was detected by the topographical portion of the MFM scan. This imperfection is most likely responsible for the pinning of the domain wall and some of the features observed in Fig. 3(c).

The tree-like domain wall dynamics are found to be irreversible in the following sense: if the magnetic field sweep is stopped and reversed, existing domain walls remain at rest, and new domain walls nucleate at the edge of the sample and move toward and eventually annihilate the old domain walls. Figure 4 illustrates light "ghost" tracks that occur immediately following the passage of zigzag-shaped domain walls. These tracks require from 5 to 30 min to disappear, even without an applied field.

To summarize, we have shown the Co-Ag granular film magnetization sequence to be comprised of a large-angle magnetization rotation followed by domain wall nucleation and motion. Although a uniaxial in-plane anisotropy was detected by vector VSM measurements, a simple model including the uniaxial anisotropy would not explain the high remanence and the near 90° magnetization rotation observed for most directions of the applied field.

The domain wall pattern was observed through a complementary combination of MOIF and MFM techniques to have a fractal-like structure. The domain walls exhibited time-dependent creep in constant field, and moving domain walls were observed to leave magnetic "tracks" in the magnetization.

We thank H. J. Brown for assistance with measurements. Russian co-workers from the Institute of Solid State Physics acknowledge partial support from the International Science Foundation under Grant No. REO000.

Perpendicular spin valve behavior in a microstructured Co/Cu-Cu oxide/Co trilayer

K. Matsuyama, H. Asada, I. Matsuguma, T. Saeki, and K. Taniguchi

Department of Electrical Engineering, Kyushu University 36, Fukuoka 812, Japan

In this article we report a perpendicular spin valve behavior in a microstructured noncoupling magnetic trilayer system of Co/Cu-Cu oxide/Co. The Co thin films having markedly different coercivity H_c were prepared with a vacuum evaporation with electron beam ($H_c = 20\text{--}30$ Oe) and rf sputtering ($H_c = 90\text{--}260$ Oe), which enables the selective switching of the magnetization in the base and counter Co layers. The film surface of the Cu was oxidized by the rf sputter etching, which results in the increase of the resistance for the perpendicular current and enables measurements of the perpendicular spin valve behavior at room temperature. The additional spacer layer of sputtered SiO_2 with a contact hole of $5\text{ }\mu\text{m}$ diameter was fabricated with photolithographic method between the bottom Co and the intermediate Cu layer, which defined the current path perpendicular to the film plane. The measured magnetoresistance ratio was 0.85% ($dR=7.6\text{ m}\Omega$, $R=0.89\text{ }\Omega$) at room temperature. © 1996 American Institute of Physics. [S0021-8979(96)40508-0]

I. INTRODUCTION

Studies on the magnetoresistance (MR) in a current perpendicular to the film plane (CPP) are believed to provide a fundamental insight into spin polarized electron transport. One of the difficulties in the experiments on CPP MR is to detect a very small resistance due to the particular current path geometry. The use of superconducting electrodes¹ or the microfabrication techniques^{2,3} have enabled the experiments on CPP MR. The other promising device structure is that it consists of ferromagnet–insulator–ferromagnet (FIF) multilayer, where the resistance for the CPP current is expected to be large due to a potential barrier at the insulating layer. The magnetic tunneling valve (MTV) effects have been observed in various FIF systems,^{4–6} where the tunneling conductance depends on the relative spin orientation in the two magnetic layers. In the previous work,⁷ we observed the MTV effect in a microfabricated FIF junction consisting of a NiFe/Al- Al_2O_3 /Co system. In the present study, the Co films were used for both magnetic layers to increase the MR ratio, considering an enhanced spin polarization in the Co.⁸ The dependence of the coercivity on a substrate temperature in the rf sputtering has been studied to realize an antiparallel spin orientation for the two Co layers. The surface oxidation layer on the intermediate Cu, produced with the rf sputter oxidation,⁹ was used as an insulating layer in this study. A CPP spin valve behavior has been studied for a microfabricated perpendicular current path with a dc four-terminal method.

II. DEVICE FABRICATION

Schematic figures for the top and cross-section view for a fabricated device are shown in Fig. 1. The designed electrode configuration allows limited components of the current contribute the voltage drop, that is, the perpendicular component to the film plane and the in-plane component parallel to the applied field H . Test chips containing six junctions were fabricated on a $1.0\times 1.0\times 0.04\text{ cm}$ glass substrate. The multilayer system of Co/Cu-Cu oxide/Co was studied in this work. The two different deposition methods of vacuum

evaporation with electron beam and rf sputtering were adopted for the fabrication of the base and counter Co layer. Representative values for the thicknesses of base Co, Cu, and counter Co layers were 0.1, 0.03, and 0.1 μm , respectively. The sputter deposited SiO_2 layer of 0.4 μm thickness was used as a spacing layer between the electrodes. The perpendicular current path was confined with a fine contact hole of 5 μm diameter in the SiO_2 insulating layer.

Microfabrication techniques used in this study are as follows. Lithography for electrodes and the contact hole was performed by the ion milling, with 600 V Ar of 0.6 mA/cm^2 current density, using a photoresist mask. A leak free insulation by the SiO_2 spacing layer was confirmed by a process test chip with no contact hole. A dummy substrate was also used to detect the milling end point to produce a contact hole

FIG. 1. Configuration of a microstructured device for measurement of CPP MR behavior. (a) Top view of device and experimental setup. (b) Schematic cross-section view.

FIG. 2. SEM photographs of a fabricated device. (a) Whole view of device. (b) Contact hole produced in a SiO_2 spacing layer.

with the designed thickness. The spacer layer SiO_2 was deposited on the dummy substrate, with a predeposited thin metal film of $0.01 \mu\text{m}$. The milling end was detected by observing the disappearance of under coated metal film in the dummy one. There is no significant influence on the MR behavior due to the overmilling of $0.01 \mu\text{m}$ on the bottom electrode of the Co layer. The rf sputter etching in oxygen plasma was adopted for producing the Cu oxidation layer; typical oxidation parameters used were oxygen pressure of 50 mTorr and rf power density of 0.4 W/cm^2 . Immediately after the oxidation, the rf power was switched from the substrate holder to the cathode with Co target for the counter layer deposition. A 10 min backsputter was performed for the surface cleaning with 0.8 W/cm^2 rf power and 40 mTorr Ar pressure, before the deposition of Cu layer and the sputter oxidation of the Cu layer. SEM photographs of whole view and the contact hole of the fabricated device are shown in Fig. 2. The fine contact hole with the flatly shaped bottom surface was successfully produced by the Ar ion milling. Protubercles at the contact hole edge would be formed by the redeposition of the sputtered SiO_2 .

The Co films with lower coercive field of 20–30 Oe were deposited by an e -gun type vacuum evaporation system with the following parameters: base pressure $< 3 \times 10^{-6}$ Torr, deposition rate 0.4 \AA/s at an ambient temperature. Relatively hard Co films were deposited with a rf diode sputtering system. The dependence of the coercive field and the remanence ratio on the substrate temperature have been studied, as shown in Fig. 3. All of these samples were deposited with a rf power of 2.1 W/cm^2 and an Ar pressure of 20 mTorr, whose thickness was around $0.1 \mu\text{m}$. The prominent tem-

FIG. 3. Dependence of magnetic properties on substrate temperature for rf sputter deposition.

perature dependence of the magnetic properties would be associated with the different film structure (grain size). The substrate temperature of 150°C was adopted for the device fabrication, considering a high remanence ratio, which leads to a well defined antiparallel magnetization configuration in the remanent state. Saturation induction $4\pi M_s$ for the evaporated and the sputtered Co were 14–15 kG and 11–13 kG, respectively. The lower saturation induction in the sputtered Co would be due to the inclusion of Ar during the deposition.

III. RESULTS AND DISCUSSIONS

Figure 4 shows a M - H hysteresis for a trilayer sample prepared simultaneously with the device, except that no photolithographic process was performed on it. The asymmetry in the hysteresis could be ascribed to the oxidation of Co at the surface or the interface between the oxidized Cu layer. The difference of the coercive field between the single layer (Fig. 3) and trilayer sample can be ascribed to the difference of under layer, that is, the former is sputtered on the glass substrate, while the latter on the oxidized Cu layer. The appearance of the intermediate shoulder in the M - H hysteresis confirms the selective switching in the two Co layers. However, a not so sharp intermediate shoulder suggests an occurrence of cooperative magnetization switching in the two layers, which would be caused by a local ferromagnetic exchange coupling or a magnetostatic interaction between them.

A measured MR hysteresis for the fabricated device is shown in Fig. 5. A comparison between the M - H and MR hysteresis confirms the dependence of the resistance on the relative angle between the magnetization direction in the two

FIG. 4. M - H hysteresis curve for a Co (evaporated)/Cu-Cu oxide/Co (sputtered) trilayer film.

FIG. 5. Magnetoresistance hysteresis measured at room temperature for a perpendicular current confined with a 5- μm -diam contact hole.

Co layers. However, the complicated magnetization switching behavior suggested in the MR hysteresis was not observed in the M - H hysteresis. We suspect that the MR hysteresis is related to the switching of the magnetization direction in the local region where the thickness of the CuO insulating layer is relatively thin, while the M - H hysteresis presents the averaged magnetization. Another probable cause for the difference is the change of the magnetic properties due to the fabrication process.

The anisotropic MR (AMR) caused by in-plane components of the current is expected to decrease the resistance from the saturation value in our electrode design, where the saturated magnetization direction is parallel to the in-plane current direction. Thus, the increase of the resistance from the saturation value, observed in the MR hysteresis, can be ascribed by assuming that the CPP MR is caused by a development of an antiparallel spin orientation in the two Co layers. Meanwhile, the AMR term appears to be negligible, since no significant decrease of the resistance from the saturation value is observed. The prominent dip of resistance (arrow 3) at around 50 Oe can be ascribed to the local switching of the sputtered (hard) Co layer. When the absolute

value of the external field exceeds 100 Oe, the resistance decreases by the magnetization switching in the hard Co layer (arrows 5, 8). The MR ratio of 0.85% has been observed at room temperature.

IV. CONCLUSION

A perpendicular spin valve behavior in a microfabricated magnetic trilayer system of Co/Cu-Cu oxide/Co has been studied using microfabrication technique. The Co thin films having markedly different coercive fields H_c were prepared by the different deposition methods of e -gun vacuum evaporation ($H_c = 20$ –30 Oe) and rf sputtering ($H_c = 90$ –260 Oe), which resulted in the selective switching of the magnetization in the multilayer Co film. The film surface of the Cu was oxidized by the rf sputter etching, which results in the increase of the junction resistance and enables measurements of the perpendicular spin valve behavior at room temperature. The microstructured current pass perpendicular to the film plane was confined with a contact hole of 5 μm diameter produced in the SiO_2 spacer layer with an Ar ion milling. The magnetoresistive hysteresis measured by a dc four-terminal method confirms the spin valve properties in the perpendicular current through the contact hole. The measured magnetoresistance ratio was 0.85% ($dR = 7.5$ m Ω , $R = 0.89$ Ω) at room temperature.

We present a crystallographic template for the growth of the range of Fe-N phases on Si(001) by lattice matching on selected underlayers. Epitaxial films of pure α -Fe, γ' -Fe₄N, and α' -Fe₈N (N martensite) were grown individually by the optimization of reactive N₂ sputtering parameters. The orientation relation of the Fe-N phases was Fe-N(001)||Ag(001)||Si(001) and Fe-N[100]||Ag[110]||Si[100]. Annealing the α' -Fe₈N films resulted in the formation of α' -Fe₈N/ α'' -Fe₁₆N₂ mixtures. In addition to the crystallographic and structural analysis, quantification of x-ray diffraction peak intensities confirmed that the α'/α'' mixtures contained as much as 46 vol % α'' (remaining α'). Vibrating sample magnetometry and SQUID magnetometry measurements of the α' and α' (54%)/ α'' (46%) mixture, respectively, indicate enhanced magnetic moments for both the α' and α'' phases with respect to pure Fe. © 1996 American Institute of Physics. [S0021-8979(96)05108-X]

I. INTRODUCTION

It has been claimed that α'' -Fe₁₆N₂ possesses a giant magnetic moment.¹ After two decades, this claim is still under considerable scrutiny. The controversy is fueled by the widely varying magnetization values observed by different workers, and by the lack of reproducible single-phase α'' . In 1972 Kim and Takahashi produced thin films by evaporating iron in nitrogen which had a magnetization as high as 2.64 T.¹ The films were predominately α -Fe, and the magnetization of α'' -Fe₁₆N₂ was inferred to be 2.76 T (295 emu/g). Unfortunately, they were not able to reproduce their results,² and Fe₁₆N₂ was forgotten for nearly twenty years until pure α'' films on In_{0.2}Ga_{0.8}As(001) and Fe/GaAs(001) with giant moments of 2.9 T (310 emu/g) were reported by Sugita and co-workers.^{3,4} Attempts at growth on simpler substrates have resulted in only a modest enhancement in moment and often in multiphase mixtures. While the giant moment has been claimed in bulk α'' as well,⁵ the moment was extracted from mixed-phase samples in which volumetric analysis is problematic. Mixed phases are commonly observed in the complicated Fe-N phase diagram and, consequently, γ' -Fe₄N and/or α -Fe either accompany or are formed preferentially to the metastable α'' -Fe₁₆N₂ phase. Theoretical calculations based on the band structure of Fe₁₆N₂ predict values for the magnetization around 2.4 T (~260 emu/g),⁶⁻⁹ well below Sugita's claims, but consistent with the magnetizations reported by several other workers.¹⁰⁻¹²

Jack first proposed the structure of Fe₁₆N₂ in 1951.¹³ The iron structure is body-centered tetragonal ($a=5.72$ Å, $c=6.29$ Å) with nitrogen atoms occupying every other octahedral site. It is formed by annealing the metastable nitrogen martensite, α' -Fe₈N, in which the nitrogen occupation is randomly distributed in the octahedral sites of a similar bct structure ($a=2.84$ Å, $c=3.14$ Å). Magnetic property measurements of single-phase Fe₁₆N₂ are needed to confirm the giant moment in α'' . Therefore, we attempted deposition of

α'' using a commercially relevant substrate with an uncomplicated template and process. We report the structural and magnetic characterization of systematically grown Fe-N phases on Si(001).

II. EXPERIMENT

Epitaxial iron nitride films were deposited by conventional reactive (N₂) dc magnetron sputtering on Si(001). The substrates were cleaned in a standard sulfuric acid process, followed by hf etching of the native oxide layer and hydrogen passivation of the surface. Substrates were loaded immediately into the vacuum chamber and were not heat treated. Base vacuum was at least 1.2×10^{-7} Torr. The crystal structures were characterized using a Siemens D5000 x-ray diffractometer with Cu K α radiation. Magnetization data for α -Fe, γ' -Fe₄N, and α' -Fe₈N were acquired at room temperature for fields up to 10 kOe applied parallel to the film plane using a 2 T EG&G PARC vibrating sample magnetometer. Magnetization data for α' -Fe₈N/ α'' -Fe₁₆N₂ mixtures were acquired at 15 K for fields up to 15 kOe using a 5.5 T Quantum Design SQUID magnetometer. Orientation relationships were determined by selected-area electron diffraction in a JEOL 200CX transmission electron microscope.

III. RESULTS AND DISCUSSION

Growth of Fe₁₆N₂ on MgO(001) using an Fe seed layer and Ag underlayer has been reported recently.¹² Ag(001) has a 1% lattice mismatch with α'' -Fe₁₆N₂(001) when it acquires an in-plane rotation of 45°, i.e., when Fe₁₆N₂[100]||Ag[110]. A similar epitaxy can be achieved with Si(001), i.e., Ag[100]||Si[100], but with a somewhat larger lattice mismatch of 6.4%. These orientation relationships were used sequentially to generate a template [Fig. 1(a)] for the epitaxial growth of the Fe-N phases with a c -axis normal. Further, the growth of individual Fe-N phases (α -Fe, γ' -Fe₄N, and α' -Fe₈N) was accomplished by the optimization of substrate temperature, sputtering rates and gas flow rates. Silver was deposited directly on Si(001) at 100 °C by rf magnetron

FIG. 1. (a) Epitaxial template for $\text{Fe}_{16}\text{N}_2(001)$ growth on $\text{Ag}(001)$ underlayers on $\text{Si}(001)$ substrates. $\text{Fe}_{16}\text{N}_2[100]\|\text{Ag}[110]\|\text{Si}[100]$, and (b) plan-view TEM diffraction pattern of an $\text{Fe}_8\text{N}/\text{Ag}$ free-standing film.

sputtering in argon (3 mTorr), with a thickness of 1000 Å and growth rates ranging from 0.3 to 5.0 Å/s. All Fe-N films were deposited by dc magnetron sputtering at a growth rate of 0.5 Å/s within a thickness range of 600–1000 Å. Pure α -Fe was grown at 25 °C in argon. γ' - Fe_4N was grown at 100 °C in a mixture of Ar and N_2 with a ratio of 46/5 sccm. α' - Fe_8N was grown at 45 °C with an Ar/ N_2 ratio of 46/4 sccm. α' films were annealed at 150 °C for 2 h in vacuum (at least 10^{-6} Torr) to produce an α'/α'' mixture. The growth configuration of α' - Fe_8N was confirmed by electron diffraction of plan-view samples in a transmission electron microscope (TEM). The diffraction pattern shown in Fig. 1(b) is a superposition of patterns from individual Fe_8N and Ag layers. We deduced the orientation relationship to be $\text{Fe}_8\text{N}[100]\|\text{Ag}[110]$.

X-ray diffraction spectra of α , γ' , α' , and α'/α'' films are shown in Fig. 2. The Ag underlayers, deposited at growth rates around 5 Å/s, are of good quality with strong (001) epitaxy. Fe-N films are also epitaxial but have broader peaks. The integrated intensity in x-ray scattering is given by $I_{hkl} = A |F_{hkl}|^2 L_p P$,¹⁴ in which A is a constant, L_p the combined Lorentz and polarization factor, and P the multiplicity factor. The Lorentz factor, $\cos \theta (1/\sin 2\theta)^2$, is modified to

FIG. 2. XRD patterns of Fe-N films grown on $\text{Ag}/\text{Si}(001)$; (a) γ' - Fe_4N , (b) α -Fe, (c) α' - Fe_8N , and (d) α' - $\text{Fe}_8\text{N}/\alpha''$ - Fe_{16}N_2 .

FIG. 3. XRD pattern of α' - Fe_8N deposited and annealed as in Fig. 2(d); (a) Ag deposited at 5.2 Å/s and (b) Ag deposited at 1.9 Å/s.

$(1/\sin 2\theta)^2$ since the $\cos \theta$ term is only included for randomly oriented specimens. The polarization factor is unity for monochromatic radiation, and the multiplicity is unity for an oriented specimen. The structure factors were calculated using formulas derived by Nakajima and Okamoto,¹⁵ and atomic scattering factors for Fe and N were those reported by Cullity.¹⁴ Calculations were based on an ideal structure in which the Bragg angles (θ_B) are 14.2° and 29.4° for $\alpha''(002)$ and $\alpha''(004)$, respectively. The sample area was large compared to the beam size, but the thickness was smaller than the effective x-ray penetration depth. Therefore, the integrated intensity was multiplied by the factor $G = 1 - \exp(-2\mu t/\sin \theta_B)$,¹⁴ in which μ denotes the line absorption coefficient. We calculated the ideal integrated intensity ratio, $I_{\alpha''(004)}/I_{\alpha''(002)}$, to be 5.8 for a single-crystal α'' film. In addition, to determine the volume fractions of α' and α'' , we obtain the ideal $I_{\alpha'(002)}/I_{\alpha''(002)}$ integrated intensity ratio for a 50/50 wt % mixture of α' and α'' , since α' and α'' have different scattering intensities for the same mass. Using similar parameters and values the intensity ratio was calculated to be 9.3. It can be shown that the x-ray intensities of α'/α'' mixtures satisfy the relationship

$$\frac{I_{\alpha''(004)}}{I_{\alpha''(002)}} + \left(\frac{1-x}{x} \right) \frac{I_{\alpha'(002)}}{I_{\alpha''(002)}} = \left(\frac{I_{\alpha'(002)} + I_{\alpha''(004)}}{I_{\alpha''(002)}} \right)_{\text{expt}}$$

in which x is the mass fraction (and volume fraction if one assumes similar densities for α' and α'') of α'' . The left side of the equation contains the calculated ratios while the right side contains the measured ratio. Using the above formula and the experimental data, the α'/α'' mixtures were estimated to be 46 vol % α'' .

The nature of annealed α' films is affected by the silver morphology as well as the annealing temperature and duration. In Fig. 2(c), the data represent an α' film grown on Ag deposited at 5.2 Å/s. An α' film grown under the same conditions except for the Ag deposition rate (1.9 Å/s), showed similar x-ray characteristics. Upon annealing at 150 °C for 2 h, however, the resulting α'/α'' mixtures varied in quality and purity. Compared to the spectra in Fig. 2(d) [reproduced in Fig. 3(a)], the x-ray diffraction (XRD) spectra in Fig. 3(b) indicates a film containing a similar α'/α'' ratio mixed with a small amount of α -Fe. Work is in progress to better understand the effect of silver morphology and texture on nitrogen

FIG. 4. VSM hysteresis loops of (a) α -Fe, (b) γ' -Fe₄N, and (c) α' -Fe₈N, normalized with sample mass.

ordering and phase separation. In general, annealing temperatures above 150 °C resulted in phase separation of α' into γ' -Fe₄N and α -Fe.

Vibrating sample magnetometry (VSM) data acquired at room temperature and normalized with sample mass are shown in Fig. 4. Assuming a magnetization of 217 emu/g for α -Fe [Fig. 4(a)], the film mass was estimated. The film thickness was then calculated from the estimated mass, area and density, and was used as a calibration for γ' -Fe₄N (including volume expansion), since the α and γ' films were grown under identical sputtering conditions. The γ' magnetization was then estimated to be 205 emu/g [Fig. 4(b)]. These moments are based on ideal structures and densities, which have not been confirmed beyond the x-ray analysis. The thickness of α' -Fe₈N was measured with a profilometer and α' was estimated to have a moment of 240 emu/g [Fig. 4(c)]. The film thickness after annealing was assumed to be approximately the same as the single-phase α' . Figure 5 shows normalized SQUID magnetometry data taken at 15 K for the α'/α'' film shown in Fig. 2(d). We estimate that the moment of the α'/α'' film is also around 240 emu/g. These magnetic moments vary widely (± 20 emu/g) depending on the mass estimates used for each film. More accurate mass and density measurements are underway. In addition, nitrogen contents of the films are still to be determined.

IV. CONCLUSION

We have successfully grown several phases (α , γ' , α' , and α'') of the Fe-N system epitaxially on a technologically relevant substrate using a reactive sputtering process. Growth conditions were optimized and the orientation relationships were confirmed. The growth of the α'' -Fe₁₆N₂ phase was ac-

FIG. 5. SQUID magnetization data for an α' -Fe₈N/ α'' -Fe₁₆N₂ mixture, normalized with sample mass.

complished only as a mixture with α' -Fe₈N; however, the exact ratio of the two phases was determined (46% α'' , remaining α') by a refinement of x-ray diffraction intensities. Our preliminary results indicate an enhancement in the moment with respect to pure α -Fe. Further characterization of the magnetic structure of these films by Mössbauer spectroscopy will be reported in the near future.

The magnetic properties of nanometer-scale particles are studied using the protein-complex ferritin as a vesicle for either an antiferromagnet or a ferrimagnet. For antiferromagnetic ferritin particles, the anisotropy energy is found to depend linearly on the particle volume, suggesting that bulk anisotropy dominates over surface anisotropy. Effects due to the bulk and surface spins are discerned at high magnetic fields (27 T). At very low magnetic fields (1 nT) and temperatures (20 mK), the tunneling frequency of the Néel vector is observed to scale exponentially with the particle volume, consistent with the linear dependence of the anisotropy barrier on volume and with theories of macroscopic quantum coherence. In the ferrimagnetic particles, the anisotropy barrier decreases for smaller particles while simultaneously displaying a slight increase in coercivity and a dramatic decrease in the remanence over three orders of magnitude. © 1996 American Institute of Physics. [S0021-8979(96)05208-6]

Ferritin is a versatile system in which to study magnetism on the nanometer length scale. The globular apoferritin protein shell has an ~ 8 -nm-diam cavity which can serve as a host for a variety of materials. In natural ferritin, the core is composed of an antiferromagnetic iron oxide hydroxide similar to the mineral ferrihydrite.^{1,2} The cores can also be artificially reconstituted within the intact apoferritin with control of the particle volume from 100 to 3000 iron ions per core.³ Alternatively, the cores can be synthesized with a ferrimagnetic compound such as magnetite or maghemite to produce "magnetoferritin."⁴ Thus we control both the magnetic state and the particle size.

For the present study, a series of antiferromagnetic and ferrimagnetic samples are prepared with iron loading per core ranging from 100 to 3000 ions. The loading is determined by measurements of the iron content using atomic absorption analysis and by measurements of the protein concentration using the Lowry method.³ Designations of the samples by iron loading therefore represent an average number of iron ions per protein. The core diameters are also measured by transmission electron microscopy (TEM). Prior to any magnetic measurements, all samples are dried in air at temperatures not exceeding 40 °C. A sample of natural horse spleen ferritin is also studied for comparison with the artificial samples. Initial characterization is performed with an rf SQUID magnetometer at temperatures from 2 to 300 K and fields up to 5 T. Measurements at higher fields to 27 T utilize a microfabricated cantilever magnetometer.⁵ To study the dynamics of tunneling at temperatures as low as 20 mK and fields of ~ 1 nT, an integrated dc SQUID susceptometer is employed.⁶

All the antiferromagnetic and ferrimagnetic samples are superparamagnetic at temperatures above 100 K. A comparison of the magnetization of the two types of samples is shown in Fig. 1 at 5 K, a temperature below the blocking temperatures T_B at 50 mT of both the antiferromagnet and ferrimagnet samples (10.5 and 40 K, respectively). The anti-

ferromagnetic ferritin has a weaker moment but a larger coercive field. The shape of the two curves is also significant: the antiferromagnet does not saturate even in a field of 27 T (Fig. 2), whereas the ferrimagnet saturates at rather modest fields (<0.5 T). This is due to the fact that the magnetization measured in the former is a sum of different contributions from the antiferromagnetic core (the bulk spins) and an uncompensated surface moment,⁷⁻⁹ whereas in the ferrimag-

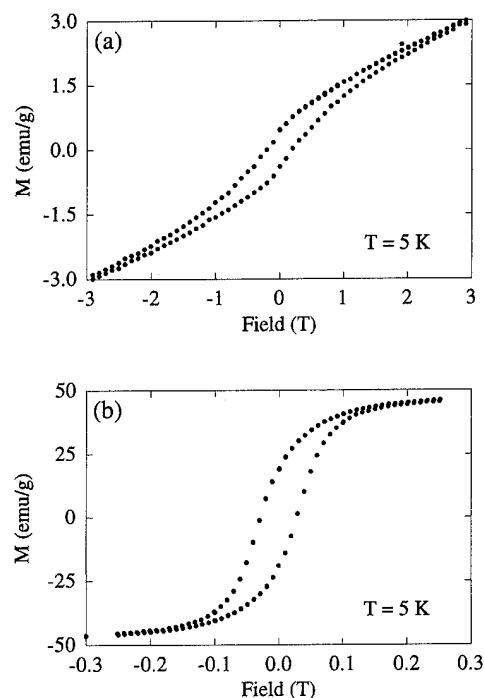

FIG. 1. Magnetization vs field for (a) the natural horse spleen ferritin (~ 2000 iron ions/particle) and (b) the ferrimagnetic artificial ferritin-“magnetoferritin” (3100 iron ions/particle). Note the difference of an order of magnitude in both the x and y scales. The sample quantities are on the order of 250 μ g.

FIG. 2. Magnetization of the natural horse spleen ferritin using a cantilever magnetometer compared with the scaled measurement from the rf SQUID. The magnetization is normalized by the value at 27 T. The hysteresis is not visible on this scale.

netic sample the bulk and surface spins appear to contribute in the same manner to the magnetization. Previous high-field measurements suggested a saturation of the moment followed by a discontinuity interpreted as a spin-flop transition.¹⁰ When the high-field data are properly normalized, however, the moment does not saturate by 27 T, and there is no discernible discontinuity in the magnetization curves. Nevertheless, the magnetization at high fields still does not linearly extrapolate to zero, implying that the susceptibility of the surface remains substantial compared to that of the bulk at all fields examined.

Below the blocking temperature, while the magnetization may be classically forbidden from crossing over the anisotropy energy barrier, it may coherently tunnel through the barrier, producing a resonance in the magnetic susceptibility or noise.¹¹ This quantum reversal mechanism is favored for antiferromagnets over ferrimagnets, and furthermore, the resonance frequency depends exponentially on the magnitude of the energy barrier.^{12,13} In turn, the energy barrier depends on the volume of the particles, and if the latter dependence could be established by independent means, then one could test the theories of macroscopic quantum coherence. Through measurements of the blocking temperature with an rf SQUID magnetometer, we have inferred a linear dependence of the anisotropy energy barrier on the volume of the antiferromagnetic particles, which suggests that bulk and surface spins experience the same anisotropy.¹⁰ Measurements of the resonant tunneling frequency with the dc SQUID susceptometer then reveal an exponential dependence as seen in Fig. 3(a).

It is interesting to draw a comparison between the observation of blocking in the regime of a few K and the appearance of coherence in the mK regime. Note that the blocking temperatures are obtained in the presence of a magnetic field on the order of 10 mT. As seen in Fig. 3(b), the blocking temperature can be reduced by decreasing the applied field. (The blocking temperature can also be reduced by increasing the field above the coercive field.) In contrast, the frequency dependent susceptibility measurements are performed with a field on the order of nT and at temperatures as low as 20 mK, a difference of seven orders of magnitude in field and three orders of magnitude in temperature. An attempt to extrapolate from 10 mT to 1 nT and from 10 K to 20 mK would

FIG. 3. (a) Dependence of the resonance frequency in the magnetic noise on the size of antiferromagnetic particles, as obtained with an integrated dc SQUID susceptometer. The volume has been normalized by V_0 , the volume of the largest particles studied (~ 4500 iron ions/particle). The line is a guide to the eye. (b) The variation of the blocking temperature in the (antiferromagnetic) natural horse spleen ferritin vs applied field.

obviously be questionable. Although the dynamics would most likely change over such a large range, it is not possible to conclude from measurements at 10 mT and 10 K whether the particles are blocked in the classical sense at 1 nT and 20 mK.

Moreover, the measurements of the amplitude of the ac susceptibility¹⁴ demonstrate that coherence vanishes for fields exceeding ~ 100 nT. Similarly, if the sample is not diluted at least by a factor of 1000, the dipolar couplings completely suppress the coherence.¹⁵ Thus the experimental condition under which the blocking temperature is measured (high fields and low dilution) is such that the quantum two-level system is detuned and no coherence can develop under these conditions, even if the observation temperature is lowered far below the blocking temperature. The fact that the blocking temperature is much higher than the cross-over temperature which is observed in the ac susceptibility data (low fields and high dilution) is indeed compatible with the interpretation of the resonance as macroscopic quantum coherence.

Most of the work thus far has focussed on the antiferromagnetic ferritin. More recent work has sought to elucidate the size dependence of the magnetic properties of the ferrimagnetic ferritin (magnetoferritin) to complement the initial measurements of the fully loaded particles.^{10,16} Anisotropy

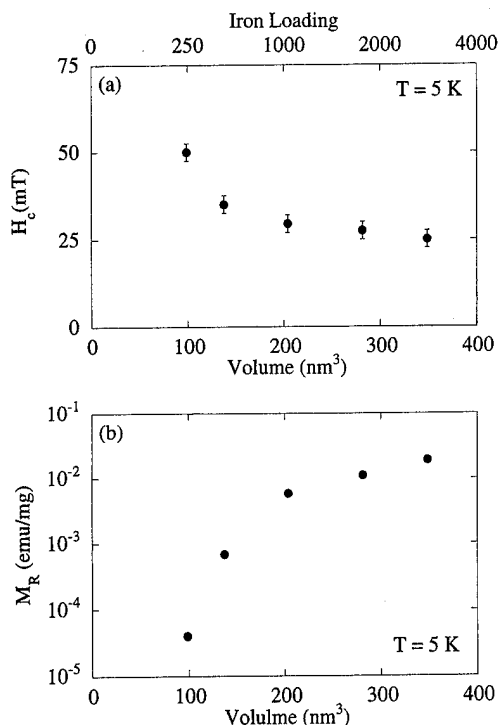

FIG. 4. The (a) coercivity and (b) remanence of the magnetoferritin samples at low temperatures.

was previously observed in magnetoferritin in the difference between field-cooled and zero-field-cooled temperature sweeps but not resolved in the field sweeps.¹⁰ In Fig. 1(b), the anisotropy results in hysteretic field sweeps when observing on a field scale ten times finer than for the antiferromagnetic sample. There is no anomaly in the remanence up to 150 K implying there is no Verwey transition.¹⁷ This observation, together with Mössbauer data,¹⁸ suggests that the mineral in the magnetoferritin is maghemite instead of magnetite, which could not be formerly distinguished by x-ray diffraction. Like the natural ferritin, the magnetoferritin also displays an increase in the blocking temperature with decreasing volume from almost 10 to 100 K for iron loading from 100 to 3100 ions, respectively.

The larger moment of the magnetoferritin as compared to the antiferromagnetic ferritin allows for a more complete study of hysteresis over the entire range of samples. First, the field required to saturate the moment is found to increase as the particle volume decreases. This is consistent with a decrease in the moment per particle for superparamagnetic particles whose magnetization is well described by a Langevin function. Second, the coercive field is observed to increase as the volume decreases [Fig. 4(a)]. There are two possible explanations for this effect: (1) the likelihood of forming magnetic domains becomes less favorable as the volume decreases, or (2) if the anisotropy constant K does not change,

the decrease in the moment M implies an increase in the coercive field $H_c = 2K/M$ for coherent reversal of magnetization within the Stoner–Wohlfarth model. Finally, the remanence is found to decrease by three orders of magnitude while the volume changes by less than one order of magnitude. Thus the stability of the particles is extremely sensitive to the size of the particles.

While the present work has involved iron oxides, ferritin can also serve as a host for iron sulfide^{19,20} or even manganese and uranium oxides.^{19,21} The magnetic properties of the latter are as yet unexplored. Ferritin also has potential in biological applications since the protein shell makes the mineral cores compatible with living organisms. One example is as a site-specific contrast agent for magnetic resonance imaging.¹⁶ Thus ferritin will likely continue to be of interest to basic and applied studies of magnetism on the nanometer scale.

Longitudinal magnetic recordings written on high coercivity medium ($H_c = 2500$ Oe) were investigated using magnetic force microscopy (MFM). Recorded tracks with bit density up to 6000 fr/mm were investigated. A variety of qualitative information about the recorded tracks and domain structure in the medium was obtained. It was determined that the recorded bits strongly interacted with domains in the medium at the track edges, causing severe jitter. Also bit bending due to the head field was observed. A new method for the quantitative analysis of recorded tracks was used. Using this method, recording signal and medium signal-to-noise ratio were calculated from MFM data. Parameters obtained in this way showed excellent agreement with signal and signal-to-noise ratio obtained from the recording measurement using a MR head. © 1996 American Institute of Physics. [S0021-8979(96)09308-X]

I. INTRODUCTION

Ultra-high density magnetic recording at recording densities of 10 Gbits/in.² and higher will be achieved only if basic understanding of media noise is achieved. Media noise is a material property that depends strongly on the magnetic microstructure of the medium. Newly developed magnetic force microscopy (MFM)¹ provides a unique opportunity to study both qualitatively and quantitatively the micromagnetic structure of the material as well as magnetic bits recorded on such a medium.^{2,3}

There have been a number of reported qualitative studies of magnetic recording using MFM.² Quantitative description of MFM images was usually limited to the estimation of bit and domain sizes. However virtually no attempts were made to obtain signal, noise, or any other quantitative recording information using MFM scans.

The purpose of this article is to present the results of the qualitative and quantitative MFM investigations of recording properties of high coercivity longitudinal media.

II. EXPERIMENTAL PROCEDURE

The magnetic recording patterns (all-ones) were recorded on commercially supplied, prototype, high coercivity, planar isotropic longitudinal media in the as-deposited, demagnetized state. The medium had coercivity $H_c = 2500$ Oe and remanent magnetization-thickness product $M_r \delta = 0.65$ memu/cm². Carbon overcoat thickness was 7.5 nm. The standard noise measurements were performed, using a MR-read

head. The head gap width was 0.2 μm and the flight height was 49 nm. The recorded patterns were observed in MFM with an ac detection scheme² using a tip lift of 80 nm. The MFM tip was coated with thin CoCrPt/Cr and magnetized in the transverse (perpendicular to the sample plane) direction. Thus the contrast in the MFM scans arose mainly due to the z component of the stray magnetic field from the medium.²⁻⁵ Therefore the highest MFM signal from recorded track was detected at the magnetic transitions. This contrast was used

FIG. 1. A method for measuring recording signal and signal-to-noise ratio using MFM.

FIG. 2. MFM images of the examined tracks. Linear recording densities are given in the figure.

to measure the "MFM-recording" signal, media noise and signal-to-noise ratio. The method of signal and signal-to-noise calculation is explained in Fig. 1. The profile of the magnetic signal was averaged across the recording track. The averaging box was $2.9 \mu\text{m}$ across the track and included ~ 15 transitions along the track. The recording tracks with densities >1000 fr/mm were quantified. The recording signal amplitude (MFM signal) was calculated as R_z of such a profile. The R_z parameter is defined as the average peak to peak value for five highest peaks and five lowest valleys. The medium noise was estimated from the fast Fourier transform (FFT) of the averaged profile. The noise N was calculated by integrating the noise spectrum from FFT, discarding the signal peaks, and dividing it by the band width. The MFM signal-to-noise ratio was calculated as

$$S_0/N = 20 \log(R'_z/2N), \quad (1)$$

where R'_z was the MFM signal for the isolated transitions.

Thus calculated recording parameters were compared with corresponding parameters from recording experiments using a recording head.

It should be noted the noncontact mode in the scanning probe microscope, using a magnetic tip may sense both magnetic (MFM) and height information (AFM). The comparison between AFM and MFM data from the same area of the

FIG. 3. MFM images of high density patterns with enlarged track edge images; (d) MFM image and corresponding FFT pattern (upper left corner) from the unrecorded part of the disk.

sample showed complete separation of magnetic and height signal for the microscope settings used in the experiments.

III. RESULTS AND DISCUSSION

Tracks with longitudinal patterns recorded with densities from 100 to 6000 fr/mm are shown in Figs. 2 and 3. The bright and dark lines are clearly visible inside all the tracks. These lines correspond to the magnetic flux coming up from the transition or going down to the transition.² Also, a fine magnetic contrast in the unrecorded background and in the magnetic bits area is quite visible.

A. Qualitative MFM analysis

The recorded tracks had a width of $\sim 3.9 \mu\text{m}$. The transitions recorded at low densities were clearly curved at the track edges. The curvature was observed also at higher recording densities (>3000 fr/mm) but it appeared to be smaller. The curving bits and an asymmetry in the magnetic contrast at the track edge (one side clearly darker) were probably due to the geometry of the head resulting in a specific writing field gradient.⁶ The bits (magnetic transitions) interacted with the magnetic domain walls in the background. This effect was most visible at the track edges of high density tracks (Fig. 3). It was observed that the bits at track edges were bent towards the magnetic transitions with the same sign present in the unrecorded background and vice-versa. This caused a severe jitter at the track edges. All the observed track-edge effects suggest that the track width used for reading should be smaller than the total track width to avoid reading errors.

Some degree of percolations was observed in between the recording transitions written with densities ≥ 4000 fr/

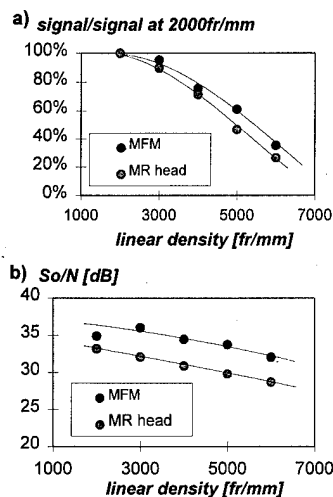

FIG. 4. Results of recording measurements using MFM compared to the results of measurements using MR-head: (a) normalized signal; (b) medium signal-to-noise ratio.

mm. The number of percolations increased with the recording densities. At 6000 fr/mm recording density "bridges" between transitions with the same sign were clearly visible. Such bridges resulted from the interactions between parts of the transitions.

Also a MFM image was scanned from the unrecorded part of the disk in between the tracks [Fig. 3(d)]. The image consisted of elongated bright and dark features of $\sim 0.5 \mu\text{m} \times 2 \mu\text{m}$. Also some smaller features can be observed in the MFM scan. The smallest magnetic contrast features observed in the image were $\sim 150\text{--}200 \text{ nm}$ and were estimated from the FFT pattern. Slight directionality observed in the FFT pattern [Fig. 3(d)] could be a result of the interaction between written tracks and intrinsic media domains.

B. Quantitative analysis: MFM "recording measurements"

The recording parameters such as read-out signal and signal-to-noise ratio were measured using MFM, as de-

scribed in Sec. II. Figure 4 shows results of the MFM analysis compared with the magnetic recording data using a recording head. The change of the MFM read-back signal with recording density shows excellent qualitative agreement with the magnetic recording data. Also the signal-to-noise ratio changes in a similar way in both MFM and magnetic recording measurement. A consistently higher S_0/N ratio (by 2–4 dB) in the MFM case was due to better sensitivity and resolution of the MFM measurement as compared to a standard reading result in a recording tester.

IV. CONCLUSIONS

Recording patterns written on high coercivity, low noise media were studied using MFM. Various track edge effects were observed, such as bending of the bits and interaction of the bits with the magnetic domains in the unrecorded background. This result suggests a need for using narrower track width for reading as compared to total track width.

A method for measuring recording parameters such as signal and signal-to-noise ratio using MFM was proposed and tested on the recorded medium. Measured parameters show that both the MFM signal and MFM signal-to-noise ratio decreased with recording density. The significant drop in signal-to-noise ratio at high densities was due to signal loss and increased noise due to percolations observed inside the track in the MFM scans. The change of MFM signal and MFM signal-to-noise ratio were in excellent agreement with the magnetic recording data obtained with MR read head. This result shows that the proposed MFM magnetic recording read-out may be used for testing the media for which a suitable read-head has not yet been developed.

Grain growth and ordering kinetics in CoPt thin films

K. Barmak and R. A. Ristau

Grain growth and ordering kinetics have been studied in a 10-nm-thick CoPt alloy film of equiatomic composition annealed in the temperature range 550–700 °C by quantifying the grain size, grain size distribution, ordered fraction and ordered domain size. The mean grain size of the as-deposited films is 5 nm and the film is fully face-centered cubic. Upon annealing in the temperature range 550–600 °C, the mean grain size reaches a stagnation limit of 27 nm and the grain size distribution is lognormal. Grain growth resumes beyond 600 °C and the mean grain size reaches as high as 55 nm at 700 °C. Ordering occurs by nucleation and growth of $L1_0$ ordered domains, with a mean size of 3 nm at 550 °C and 19 nm at 700 °C. The ordered fraction shows a dramatic increase from 1% to ~28% between the two extremes of annealing temperature. The increase in the coercivity of the annealed films follows the increase in the ordered fraction more closely than the increase in grain size. The shape of the $M-H$ loop shows evidence of coupling between the magnetically hard (ordered) and soft (disordered) regions. © 1996 American Institute of Physics. [S0021-8979(96)09408-6]

Interest in thin film media which show high coercivity and low media noise for high density longitudinal magnetic recording is increasing. One promising material is equiatomic CoPt which has a face-centered-cubic (fcc) crystal structure in the as-deposited state, but undergoes an ordering transformation to the tetragonal $L1_0$ structure upon annealing. Recently, Coffey *et al.*¹ reported the preparation, magnetic properties and recording performance of partially ordered $M_{1-x}Pt_x$ (where M is Co or Fe, and x is 0.5) thin films with thicknesses in the range 2.5–20 nm. The samples used in the present study were 10-nm-thick CoPt films that were deposited by dc magnetron sputtering and annealed in the range 550–700 °C.

Specimens were prepared for transmission electron microscopy (TEM) by chemically back-etching the substrate and studied in a Philips EM 400T TEM/STEM. For grain

size measurements, successive bright field images of the same area were taken with the specimen holder tilt angle varying by 1° or 2°. A single, high-contrast composite tracing of the grain boundaries was made from the image series for each specimen and was entered into the LECO 2001 Image Analyzer via a video camera for grain size measurements. Several areas of each specimen were sampled in this manner until between 1100 and 1700 grains were measured. By varying the magnification of the images and/or enlargements, grains below 1 nm diameter could be reliably measured.

The ordered fraction was determined by taking the ratio of the illuminated area in a dark field image using the (110) ring, allowed only in $L1_0$ structure, to the illuminated area in a dark-field image using the (220) ring, allowed in both fcc and $L1_0$. It should be noted that in the ordered phase the latter ring is split due to a difference in lattice parameter

FIG. 1. Bright field TEM micrograph and diffraction pattern of CoPt thin film as-deposited (A) and annealed 700 °C (B). 100 nm bar.

FIG. 2. Grain size distribution plotted as $\log(d/\bar{d})$, where d is the grain size and \bar{d} the mean grain size, for anneal temperatures indicated.

between ordered and disordered phases and therefore both rings should be included. In order to compare related areas, a single dark field image was made of the entire diffraction ring at zero tilt angle using a conical scanning hybrid-diffraction unit in a Philips CM200 FEG TEM/STEM. The areas of the illuminated regions in the dark-field images were again measured by the LECO 2001. The size of the individual ordered regions was measured from the dark field images using the (110) ring.

TEM and selected area electron diffraction analysis of the as-deposited film, presented in Fig. 1(A), reveal that the film has the fcc crystal structure and is polycrystalline. After the *ex situ* anneals the grains are larger, as can be seen for the 700 °C annealed sample in Fig. 1(B), and superlattice reflections in the diffraction pattern indicate the formation of $L1_0$ ordered phase. A plot of the number of grains versus $\log(d/\bar{d})$, where d is the grain size and \bar{d} the mean grain size, reveals the distribution of grain size to be lognormal. This plot is presented in Fig. 2, which also includes the data for other samples annealed at 50 °C intervals.

The mean grain size for the as-deposited film was 5 nm with a narrow distribution between a minimum of 0.8 nm and a maximum of 12 nm. Figure 3 shows the mean grain

FIG. 3. Grain size distribution for all anneal temperatures. Horizontal line is mean size; shaded box contains 50% of population; large box 90%; bars extend to maximum and minimum values.

size and grain size distribution of the annealed films. The minimum to maximum range was 2–150 nm for 550 °C and 2–230 nm for 700 °C. From Fig. 3 it also appears that between 550 and 600 °C the mean grain size reaches a limit of 27 nm, suggesting grain growth stagnation. Grain growth resumes again beyond 600 °C. The smaller grain size of 570 and 580 °C annealed samples are believed to be a result of the presence of impurities in the annealing furnace and not a result of variations in the furnace temperature. In metals, impurities typically reduce grain boundary mobility, and thus inhibit grain growth.

Conical dark field TEM images using the ordered reflection (110) showed numerous small regions of the $L1_0$ phase for the lower annealing temperatures. The ordered domains increased in size, while their number decreased as annealing temperature was increased, consistent with a first order transformation that proceeds by a nucleation and growth mechanism. Figures 4(A) and 4(B) show the dark field images for the 600 and 700 °C annealed samples, respectively. From the

FIG. 4. Dark field TEM micrographs of $L1_0$ ordered phase for 600 °C (A) and 700 °C (B). 100 nm bar.

FIG. 5. Ordered fraction per cent (solid line), H_c in kOe (broken line) and mean grain size divided by film thickness of 10 nm (dotted line) as functions of anneal temperature. Arrows indicate expected actual H_c is higher than measured.

profusion of ordered domains at the lower temperatures we expect that each grain will have at least one ordered domain, whereas at 700 °C we observe evidence for grains which are free of ordered domains. The large scale inhomogeneity in the latter films may result in higher media noise for magnetic recording applications. Mean domain size increased from 3 nm for 550 °C to 19 nm for 700 °C anneals, as compared to mean grain size of 27 and 55 nm, respectively. The ordered fraction, plotted in Fig. 5, showed a dramatic increase from 1% for 550 °C to 28% for 700 °C.

Figure 6 presents three $M-H$ plots for the annealed films. The as-deposited film has a very low coercivity, H_c , near 20 Oe. From these $M-H$ plots it is not possible to tell whether the reduction in saturation magnetization, M_s , of the annealed films is due to a minor loop being traced at the maximum measurement field (22 kOe) of our equipment, or due to an increase in the fraction of the ordered phase which has a lower M_s than the disordered phase. When annealed

FIG. 6. $M-H$ loops at ± 22 kOe of CoPt films annealed at temperatures indicated.

above the order/disorder transition temperature of 825 °C, a recovery of sample moment can be observed, thus verifying that the reduction of M_s for 550–700 °C annealed samples is not due to film oxidation. The coercivities of the annealed samples are plotted as a function of temperature in Fig. 5 and range from near 1000 to over 12 000 Oe. We expect the actual coercivity of the 650 and 700 °C annealed films to be significantly higher.

From the data we observe that the mean grain size grows to 2.7 times the film thickness at which point growth stagnates. This stagnation of grain growth at mean grain sizes between two and three times the film thickness has been found in many studies of thin film systems² and is believed to be a result of grain boundary grooving and thus pinning of the boundaries.³ Previous studies also find that at the point of stagnation the grain size has a lognormal distribution, which agrees well with our findings. Annealing at successively higher temperatures will eventually allow the grains (or at least some of them) to become unpinned and to resume their growth. Although we find that this is indeed the case, we do not find clear evidence for secondary grain growth that has been observed in other studies.⁴ The distributions of our grain size remains lognormal with no deviation from this distribution evident at the high end. On the other hand, we find that a significant portion of the grains resist growth. The determination of mechanisms of grain growth will require extensive studies as a function of time at each annealing temperature and will be reported in future publications.

While the mean grain size grows by only a factor of 2 (27–55 nm) in the temperature range of 550–700 °C, the ordered domain size increases by a factor of 6 (3–19 nm) and the ordered fraction shows a remarkable increase from 1% to 28%. A comparison with the increase in coercivity in the same temperature range, presented in Fig. 5, shows that coercivity follows more closely the increase in the ordered fraction than the increase in grain size. The relationship between ordered fraction and coercivity has also been observed in bulk studies of CoPt.⁵ In addition, we find that even though the films are two-phased, the $M-H$ plots appear to be a single loop and not the superposition of two separate loops for a soft and hard phase. This indicates that the ordered (hard) and disordered (soft) regions are magnetically coupled (i.e., these materials are “exchange spring” magnets).⁶

It is well known that the Cr underlayer plays a critical role in generating large in-plane coercivity in Co-based magnetic thin films. In this paper we report in detail the Co-Sm ($\bar{1}100$)[0001]//Cr ($\bar{1}2\bar{1}$)[$\bar{1}01$] epitaxy revealed by high resolution electron microscopy. The lattice mismatch between Co-Sm ($\bar{1}100$) and Cr ($\bar{1}2\bar{1}$) is less than 2%, suggesting an energetically favorable configuration. The high anisotropy observed in Co-Sm films is discussed by this epitaxial relation. © 1996 American Institute of Physics. [S0021-8979(96)15308-6]

I. INTRODUCTION

In pursuing Co-based magnetic thin films for high density recording, it is well known that the Cr underlayer plays a critical role in generating large in-plane coercivity in Co-based magnetic thin films. The Co-based thin films have the hexagonal close-packed (HCP) structure which can grow on Cr underlayer epitaxially. Three kinds of microstructures in Co-based magnetic thin films with large in-plane anisotropy have been reported, which are all based on the epitaxial relation Co-alloy ($11\bar{2}0$)[0001]//Cr (001)[$\bar{1}10$]. The first kind has (001) texture of the Cr underlayer with the [010] direction randomly distributed in the film plane. Consequently the easy axes of the crystallites in the Co alloy magnetic thin films are randomly distributed in the film plane.^{1,2} The second kind has a single crystalline Cr underlayer with the (100) in film plane. The *c* axes of the hexagonal crystallites in the magnetic film are epitaxially grown in two perpendicular directions [$\bar{1}10$] and [$\bar{1}\bar{1}0$] of the Cr underlayer. Such structure has been named bicrystal.^{3,4} The third kind of microstructure is produced by depositing the Co alloy on a scratched (100) Cr single crystal. As a result, the *c* axis of the crystallites are aligned in one [$\bar{1}10$] direction only and the film has uniaxial anisotropy.⁵

Recently it has been shown that Co-Sm films with a nominal composition from Co₄Sm to Co₇Sm₂ exhibit high coercivity and in-plane anisotropy.^{6,7} Transmission electron microscopy studies of Co-Sm films have shown that the microstructure of a Co-Sm thin film is composed of the amorphous matrix and crystallites with a grain size of about 5 nm.⁸ The crystallites in the as-deposited Co-Sm films have a close-packed structure.⁹ Each crystallite has a particular stacking mode which consists of local random stacking, occasionally a few unit cells of two layer stacking *AB*, three layer stacking *ABC*, and four layer stacking *ABAC*. However, the epitaxy relation between the Co-Sm crystallites and the Cr, if any, remains a mystery. In this paper we report our discovery of a new epitaxial relation between the Co-Sm

crystallites and the Cr underlayer, that is, Co-Sm ($\bar{1}100$)//Cr ($\bar{1}2\bar{1}$) and Co-Sm [$11\bar{2}0$]//Cr [$\bar{1}11$] (equivalent to Co-Sm [0001]//Cr [$\bar{1}01$]). This epitaxy relation is responsible for the high in-plane coercivity of Co-Sm films grown on Cr underlayer with {110} texture. We think the discovery of this epitaxy relation is important also because it will now be possible to grow uniaxial anisotropic Co-Sm films (true for Co-based alloy with hexagonal close-packed structure) on single crystalline Cr of (121) surface. The resultant film will have the magnetic easy axis aligned in one direction and will have the highest anisotropy. Much higher coercivity, and coercive squareness can be expected from the uniaxial anisotropic Co-Sm films compared to current Co-Sm films.

II. EXPERIMENTAL PROCEDURE

The Co-Sm target used for deposition has a nominal composition of Co₇Sm₂. The films were deposited by dc magnetron sputtering under an Ar pressure of 5 mTorr at room temperature. The film configuration from substrate to film is 220 μ m glass, 80 nm Cr, 30 nm Co-Sm and 10 nm Cr. Cross sectional transmission electron microscope (TEM) samples were prepared by embedding the strips of the films into a 3-mm-diam Cu tube with EMBED 812 (supplied by Electron Microscopy Sciences, P.O. Box 251, Ft. Washington, Pa 19034). The Cu tube with the films was cross-sectioned into about 0.3 mm slices. The slices were dimpled to 50 μ m at the center and then ion milled until perforation. The high resolution electron microscopy (HREM) and diffraction work was performed using a JEOL 2010 transmission electron microscope operating at 200 kV.

III. RESULTS

Figure 1 shows the cross sectional HREM image of a Co-Sm film on Cr. Two Cr grains are observed. The Cr grain on the left side (marked G1) is on a random orientation and no lattice fringes are observed. The orientations of the Co-Sm crystallites with a grain size of about 5 nm grown on

FIG. 1. HREM image of a cross-sectional Co-Sm film. A Cr grain is aligned on $[111]$ zone axis while the Co-Sm crystallite is aligned on $[11\bar{2}0]$ zone axis. The epitaxy is $\text{Cr } (\bar{1}2\bar{1})//\text{Co-Sm } (\bar{1}100)$ and $\text{Cr } [111]//[11\bar{2}0]$. The interface is indicated by letter I .

this Cr grain are not identified. The Cr grain on the right side (marked G2) is aligned on the $[111]$ zone axis. The Co-Sm film grown on this Cr grain is on the $[11\bar{2}0]$ zone axis. The epitaxy is $\text{Cr } (\bar{1}2\bar{1})//\text{Co-Sm } (\bar{1}100)$ and $\text{Cr } [111]//\text{Co-Sm } [11\bar{2}0]$. The interface between the Cr underlayer and the Co-Sm film is indicated by letter I . Figure 2 is the magnified interface region shown in Fig. 1. The crystal structures of the Cr underlayer and the Co-Sm crystallite are well revealed by the optical diffraction patterns, which are attached to the corresponding regions. The optical diffraction patterns clearly show that the Co-Sm has the close-packed structure and the Cr the BCC structure. The Co-Sm layer is basically a two-

FIG. 2. Magnified interface region of Co-Sm on Cr underlayer. The stacking sequence in the Co-Sm film is well identified by the HREM image.

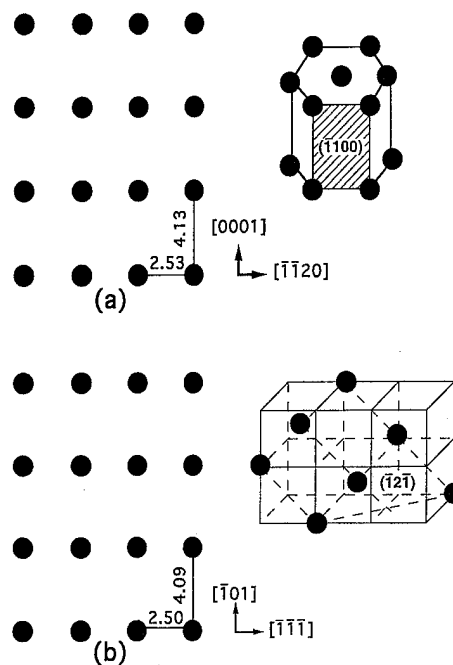

FIG. 3. Schematic illustration of atomic planes of (a) $(\bar{1}100)$ in Co-Sm of hexagonal unit cell with lattice parameters $a=0.253$ nm, $c=0.413$ nm. (b) $(\bar{1}2\bar{1})$ in BCC Cr with lattice parameter $a=0.289$ nm.

layer stacking, $ABAB$, with a stacking fault. The stacking sequence is well defined by drawing three lines corresponding to A layers, B layers, and C layers. The stacking sequence is $BABA$ on the left side and then switched to $CACA$ as indicated by the arrows. Simulated images based on the above stacking sequence for the Co-Sm crystallite and the BCC structure for the Cr underlayer show excellent match to the HREM image.

Figure 3 schematically illustrates the atomic planes of Co-Sm $(\bar{1}100)$ and Cr $(\bar{1}2\bar{1})$. The distances between atoms were deduced according to the lattice parameters $a=0.253$ nm, $c=0.413$ nm for the Co-Sm crystallite, and $a=0.289$ nm for Cr. Note that the lattice mismatch between the Co-Sm phase and the Cr is very small ($\sim 1\%$). Therefore such epitaxy is energetically favorable.

IV. DISCUSSION

The magnetic films fabricated using Co-based alloys have been available for magnetic recording for many years. The films also have the hexagonal close packed structure grown on the Cr underlayer. The epitaxy reported for the Co-alloy film on Cr underlayer is limited to Co-alloy $(11\bar{2}0)[0001]//\text{Cr } (001)[110]$. The reason that Co-alloy $(\bar{1}100)[0001]//\text{Cr } (\bar{1}2\bar{1})[\bar{1}01]$ epitaxy was not discovered by earlier researchers, if it existed in Co alloy films, is that when a $\langle 111 \rangle$ direction of Cr is aligned parallel to the electron beam, the Co-Sm $(\bar{1}100)[0001]//\text{Cr } (\bar{1}2\bar{1})[\bar{1}01]$ epitaxy is not necessarily to be seen. This is because HREM images are only obtainable for certain directions of Cr and Co-Sm crystallites. HREM images contain structural information only when the projections of the atoms are within the microscope resolution limit which is 0.14 nm for the JEOL

2010. If the projection of the atomic columns in a zone axis has a smaller spacing than 0.14 nm, no clear HREM images can be obtained. Therefore, for the Co-Sm $(\bar{1}100)[11\bar{2}0]//\text{Cr}(\bar{1}2\bar{1})[111]$ epitaxy, if the $[111]$ zone axis of the Cr grain is aligned parallel to the electron beam, both the Cr $[111]$ zone axis HREM image and the Co-Sm $[11\bar{2}0]$ zone axis image will be a projection of the structure and the epitaxy will be observed. However, for the same Co-Sm $(\bar{1}100)[11\bar{2}0]//\text{Cr}(\bar{1}2\bar{1})[111]$ epitaxy, if any of the other three $\langle 111 \rangle$ zone axis of the same Cr grain ($[\bar{1}11]$, $[1\bar{1}1]$ or $[11\bar{1}]$) is aligned parallel to the electron beam, the corresponding zone axis of Co-Sm crystallite is a high index zone axis but not a $[11\bar{2}0]$ type zone axis. In this case, high resolution image will be obtained for the Cr grain but not for the Co-Sm crystallite and the epitaxy will not be revealed. Therefore, if an arbitrary $\langle 111 \rangle$ type direction of Cr is chosen for high resolution imaging, the chance of seeing Co-Sm $(\bar{1}100)[11\bar{2}0]//\text{Cr}(\bar{1}2\bar{1})[111]$ epitaxy is one out of four.

In the x-ray diffraction spectrum of the Cr underlayer in the Co-Sm films, only strong $\{110\}$ peak is observed, suggesting an $\{110\}$ texture. The in-plane anisotropy of Co-Sm films on $\{110\}$ textured Cr underlayers can also be explained by this epitaxy relation. Figure 4 depicts the Co-Sm hexagonal structure grown on Cr underlayer with $\{110\}$ texture. The growth direction of the Cr underlayer is $[\bar{1}10]$. The two $\{112\}$ planes have a 30° angle with the $(\bar{1}10)$. Such a structure is a close approximation for the Cr underlayer morphology grown by sputtering as revealed by atomic force microscopy [10]. The Co-Sm crystallites lie on the two $\{112\}$ planes with the c easy axis 30° from the $(\bar{1}10)$ plane. However, even larger anisotropy of Co-Sm films will be expected if the $[0001]$ easy axis of Co-Sm crystallites lie in the film plane which could be achieved by depositing Co-Sm films on Cr single crystal with a (121) surface.

V. CONCLUSIONS

HREM study has clearly shown the existence of Co-Sm $(\bar{1}100)[11\bar{2}0]//\text{Cr}(\bar{1}2\bar{1})[111]$ epitaxy with a lattice mismatch of less than 2%. Such epitaxy makes it possible to grow uniaxial anisotropy Co-Sm/Cr films.

Magnetic and recording properties of monolayer and multilayer thin-film media by using composite targets

Brij B. Lal, A. Bourez, and Michael A. Russak
HMT Technology, Fremont, California 94538

A single chamber deposition process (*N*-process) to produce multilayer media was developed using a newly designed magnetron cathode. The key feature of this cathode is its use of a composite target and magnetron design which permits specific areas of the target to be independently activated. Magnetic properties, read/write performance, and media-noise of single-layer (SL) and multilayer (ML) media produced with this cathode were compared to media fabricated using a standard two chamber process (*S*-process). CoCrTa:SL-media sputtered using the *N*-process produced ~ 400 – 600 Oe higher H_c , $\sim 24\%$ lower noise, and ~ 3 dB higher SNR at 136.4 KFCI recording density in comparison to SL media sputtered by *S*-process. X-ray diffraction analysis indicated a higher degree of in-plane *c*-axis orientation in *N*-process SL media. Sputtering the magnetic layer at elevated temperature due to zero dwell time between Cr and magnetic layer deposition and the formation of preferred in-plane orientation in the magnetic layer contributed to the increase in H_c of *N*-process media. ML-media fabricated by two different sputtering processes with Cr-interlayer (Cr-IL) of 5–15 Å (1-chamber and 2-chamber) showed similar noise reduction: $\sim 30\%$ at 153.4 KFCI recording density. In addition, for the comparable H_c and $M_r t$, the ML media sputtered by *N* process produced lower pulse width (PW-50), better overwrite (OW), and lower bit shift (BS). © 1996 American Institute of Physics. I. INTRODUCTION

It is well known that the temperature at which the magnetic layer is deposited during the fabrication of Co based thin-film recording media has a strong effect on the resultant H_c and recording characteristics.^{1,2} Also, during fabrication of multilayer (ML) media the heat loss due to dwell time between each layer can affect the same parameters.^{3–5} In addition, production of ML media in a single disk system such as an Intevac MDP-350 requires several chambers to deposit the films. This contributes significantly to heat loss from the substrate. In this article we report results on media fabricated using a new cathode capable of depositing several layers of two different materials in a single sputtering chamber in an MDP-350 machine (*N*-process). This dc-magnetron cathode was used to deposit CoCrTa: single-layer (SL)- and ML media. The cathode uses concentric annular shaped targets and has the means to alternately address each portion of the target to deposit specific materials independently. Magnetic and recording properties of these SL and ML media will be presented.

II. EXPERIMENTAL DETAILS

Samples of $\text{Co}_{84.5}\text{Cr}_{12.5}\text{Ta}_3/\text{Cr:SL}$ and $\text{Co}_{84.5}\text{Cr}_{12.5}\text{Ta}_3/\text{Cr}/\text{Co}_{84.5}\text{Cr}_{12.5}\text{Ta}_3/\text{Cr:ML}$ media were sputtered on NiP/Al substrates in one chamber at 260°C with varying thickness of Cr underlayer, magnetic layer, and Cr interlayer (IL). The new cathode assembly consisted of inner (Cr) and outer (magnetic) concentric targets (Fig. 1) for depositing thin-film layers of Cr and the magnetic alloy. For the *N* and *S* processes, the dwell time between the Cr and the magnetic-layer deposition was zero and 12 s, respectively. For comparison SL media were sputtered by using the conventional *S* process. The thickness of Cr and Co-alloy films were measured by x-ray fluorescence technique and bulk

magnetic properties were measured by a vibrating-sample magnetometer (VSM). X-ray diffractometry was used to characterize film's texture. The recording characteristics were evaluated by using an inductive write head and a magnetoresistive playback head (shield-to-shield gap= $0.7\text{ }\mu\text{m}$, track width= $3.5\text{ }\mu\text{m}$). The flying height was 2.2 microinch with a linear disk speed of 8 m/s.

III. RESULTS AND DISCUSSION

A. CoCrTa/Cr:SL media

To demonstrate the effects of *N* versus *S* processes for SL media, typical magnetic properties of two groups of disks fabricated under similar sputtering conditions are summarized in Table I. These data show that for the *N*-process SL media, the increase in H_c is $\sim 20\%$ with no significant difference in squareness ratio (SR), coercive squareness (S^*),

FIG. 1. Concentric annular shaped composite targets of Cr and magnetic materials.

TABLE I. Comparison of magnetic properties for CoCrTa:SL media (magnetic film thickness: 160 Å) sputtered by *N* vs *S* processes.

Sputtering Process	VSM Data				
	H_c (Oe)	SR	S^*	OR (Mr:cr/Mr:rad)	$M_r t$ (memu/cm ²)
<i>S</i> process (conventional)	2326	0.85	0.82	1.4	0.97
<i>N</i> process (new)	2785	0.91	0.78	1.4	0.95

and orientation ratio (OR). The change in the H_c with $M_r t$ for SL media sputtered by *N* versus *S* processes is shown in Fig. 2. For both type of media, as $M_r t$ decreases, H_c increases monotonically reaching a maximum at 2338 Oe with $M_r t$:1.2 memu/cm² for the *S*-process SL media. Whereas, for the *N*-process SL media a peak in the $M_r t$ versus H_c curve was not observed within the range measured, however, a maximum value of $H_c \sim 2800$ Oe at a $M_r t$ of 0.92 memu/cm² was obtained. This means that the SL-magnetic films sputtered by *N* process approach the superparamagnetic state at a lower $M_r t$ (thinner magnetic film) than the SL-magnetic film sputtered by *S* process. In addition, for SL-media sputtered in a single chamber, we found that for a small increase in Cr-underlayer thickness from 50–100 Å, H_c increased from 1750 to 2201 Oe for media with $M_r t$:1.2 memu/cm² (Fig. 3). It should be noted that in *N* process, the magnetic layer is deposited on the Cr underlayer at a higher temperature, and also, due to zero dwell time, the Cr-underlayer film surface is not exposed to the residual gases present in the main vacuum chamber which affects the interfacial structure and chemistry for the epitaxial growth of Co-alloy film. Furthermore, higher deposition temperature produces more in-plane *c*-axis grains and promotes decoupling of the grains due to Cr segregation at grain boundaries. These observations are consistent with the earlier work reported on CoCrTa/Cr media^{6,7} where high deposition temperature and ultraclean process conditions produced high H_c due to high magnetocrystalline anisotropy and enhanced Cr-segregated grain boundary for reduced intergranular exchange coupling. Also, it was found that for comparable high-frequency (HF) amplitude, *N*-process SL media produced ~24% lower media noise and ~3 dB higher SNR
